ABSTRACT

Structural and paleomagnetic studies of Ocean Drilling Program (ODP) cores are severely hampered by the fact that the recovered cores can rarely be reoriented with any degree of confidence. Although several techniques for orienting cores have been used, none is without limitations. Core orientation devices used during drilling are expensive to operate and are usually unreliable. A common alternative, used when no core orientation tools are available, is to assume that the horizontal component of the magnetization direction of the core pointed north, and thus that features may be oriented relative to this direction. However, this neglects the effects of secular variations in the Earth’s magnetic field and of later tectonic rotation on the sample.

In this paper we outline a technique for core reorientation that matches distinctive inclined planar features measured on the core to their images on Formation MicroScanner and Borehole Televiewer wireline logs. It allows reorientation of structural and magnetic data, and hence the possibility of detecting vertical axis tectonic rotations using paleomagnetism. Its methodology is described and an example, from ODP Leg 135, presented to illustrate its application.

INTRODUCTION

Structural and tectonic information may be acquired from boreholes in two principal ways: either from structures measurable in the core itself, or from features detected on “images” of the borehole wall generated with specialty tools such as the Formation MicroScanner (FMS) (or its predecessor, the Stratigraphic High Resolution Dipmeter) and the Borehole Televiewer (BHTV). The former method has the advantage of direct observation but requires the difficult task of core orientation. In contrast, the latter method has the advantage of essentially continuous coverage and, because the logging tools in question are equipped with three-axis magnetometers, reliable orientation of observed features relative to geographical coordinates (e.g., Pezard and Luthi, 1988; Serra, 1989; Lehne, 1990). Although some mesoscale features, such as bedding and fractures, can be readily measured from downhole logs (see below), many more subtle features cannot be detected. These include, for example, paleocurrent directions, the measurement of slip lineations on fracture planes, microfabrics and preferred crystallographic orientations (e.g., Moore, 1986; Lundberg and Moore, 1986), anelastic strain measurements (e.g., Teufel, 1982), study of the relative ages of different generations of veins and their diagenetic histories (e.g., Knipe, 1986; Agar, 1990), palaeomagnetic measurements and other spatially anisotropic physical properties of the cores (e.g., seismic velocity, permeability, etc.). To consider these features in their spatial context, the borehole cores must be reoriented to geographical coordinates. Several techniques for core orientation can be used, each of which has its advantages and disadvantages. They are discussed briefly below.

CORE ORIENTATION TOOLS

Camera Multishot Tools

Oriented core may be obtained using a multishot orientation tool. In its simplest form, this device consists of a camera that is installed in a pressure housing together with a compass and pendulum, and lowered down the hole with the inner core barrel assembly. It takes photographs, at preset intervals, of the compass together with a reference line, whose orientation is determined with respect to the core. The pendulum device determines the magnitude and direction of deviation of the borehole from the vertical. Nonmagnetic drill collars must be included in the bottom-hole assembly (BHA) when the multishot tool is employed, so that the magnetic field associated with the steel drill string does not perturb the compass. Various types of reference markers are in use; these may either be grooves carved into the core with special knives set into the coring assembly (Eastman Whipstock, 1982; described in Nelson et al., 1987); or simply lines previously drawn onto core liners. The former type of marker is commonly used in the oil industry, the latter by ODP.

The more modern multishot tools used by the oil industry are designed with a nonrotating inner core barrel so that they can be used in conjunction with rotary drilling (e.g., Nelson et al., 1987; and see below); however, other multishot tools, such as the one used recently by ODP, are simpler devices that are restricted to use with hydraulic piston coring systems (Ocean Drilling Program, 1990). The latter, therefore, have the significant disadvantage of being usable only in soft, unlithified sediments from the uppermost parts of the borehole (typically <200 m below seafloor [mbsf]).

The camera multishot device has many advantages in its simplicity. Its small number of moving parts, adaptability to most gauges of core barrel, and almost real-time acquisition of results all mean that it can be widely used. However, in practice it has several, potentially serious, shortcomings that restrict its usefulness. Because of the need to use nonmagnetic drill collars in the BHA, the decision to use the multishot tool must be made before drilling begins, as it is impractical to round-trip the pipe to change the BHA at a later stage. The simple mechanical operation of the multishot tool is not infallible, and in the past, human error during installation of the system on the core barrel has resulted in misalignment of the tool by 180°. The reliability of the tool is critically dependent on the physical alignment between the groove or line on the core or core liner itself and the reference line photographed by the camera. This is dependent both upon the initial alignment of the tool upon assembly and on operating procedures. The camera itself is often a source of unreliability: films have a limited number of frames and often jam, batteries go dead, and the developed film is all too often uninterpretable. To avoid vibration corrupting the
photographic record, it is normally necessary to cease coring at the time the multishot photographs are taken. This not only wastes rig time, and is therefore expensive, but increases the likelihood of the core becoming jammed or broken. It also means that it is unlikely that oriented data will be obtained from the shallowest cores at any one site, as this is a time when the drillers are anxious to proceed with spud-in lest the unsupported BHA be sheared by flexure.

For those multishot devices used with rotary drilling, torqueing is a very severe problem. The very common observation that the reference grooves spiral up the core (e.g., Nelson et al., 1987) is evidence for the transmission of torque from the rotating outer to the supposedly nonrotating inner core barrel. If the spiralling is severe, the multishot photographs must be taken very frequently. Furthermore, if core recovery is less than 100%, significant problems are encountered in correlating the reference grooves on individual pieces of core, whose depth is not known precisely, with the rapidly changing reference direction on the multishot photographs.

**Electronic Multishot Orientation Tools**

Because of the limitations of the conventional camera-based multishot orientation tools, electronic core orientation devices have recently been developed for use in the oil industry (e.g., Sperry-Sun, 1991). A prototype is also being tested by ODP (M. Storms, ODP, pers. comm., 1993). Electronic core orientation devices are equipped with solid-state magnetometers and accelerometers in the BHA that record the orientation of the reference grooves as drilling is proceeding. The ODP tool employs scribining knives in the core catcher shoe that are physically aligned with a preset, software-driven electronic multishot system mounted at the top of the inner core barrel. To circumvent the uncertainties involved in matching the core scriber marks with the multishot record, a sonic device is employed that operates in conjunction with the multishot tool; this device monitors the amount of core that enters the core barrel with time. This allows the true location of any piece of core within the penetrated interval to be deduced, thus correlating the scribe mark on any particular piece of core with the appropriate reference knife orientation on the multishot record.

Electronic multishot tools overcome many, but by no means all, of the disadvantages of the camera-based tools. Nonmagnetic drill collars are still required. Their reliability is still low; the same difficulties are encountered in aligning the tool accurately during initial set-up, and torqueing during operations may cause further alignment problems. Integrating the data obtained from the sonic core monitor and multishot device is not straightforward and can lead to significant uncertainties. Because of these problems, and because of the considerable expense involved in operating the tool, they are not often used by commercial operators.

Under ideal circumstances, orientation errors with either the camera-based or electronic multishot tools are claimed to be in the order of ±3° (Ocean Drilling Program, 1990) to ±5° (Nelson et al., 1987), but are typically much greater under normal operating conditions. Sager et al. (this volume), for example, found an azimuthal standard deviation of ±18.6° for the camera multishot tool used with piston coring at Sites 840 and 841.

**Borehole Geometry Tool**

A modification of the multishot tools described above is the "borehole geometry tool" used by Schmitz et al. (1989) for core orientation in the IKT B pilot well in Germany. This system makes measurements of the orientation of borehole inclination, together with the angle between the "high" side of the borehole and reference grooves scored into the core in the cutting shoe. If the borehole is deviated by 1°, then the orientation of the core can be deduced. Schmitz et al. (1989) claim that gneissic foliations reoriented this way lie on average within 5° of those measured on the equivalent FMS image (see below).

**PALEOMAGNETISM**

Ideally, the horizontal components of the stable remnant magnetization vectors of samples taken from borehole cores can be assumed to indicate north at the time of formation if the magnetization was acquired during a period of normal geomagnetic field polarity (south if during a reversed polarity period), and structures may therefore be oriented relative to this direction (e.g., McWilliams and Pinto, 1988; Dick, Erzinger, Stokking, et al., 1992). Several problems, however, are inherent in using paleomagnetism in this way, not least that a strong magnetic field emanating from the drill string frequently has the effect of partially remagnetizing the samples, giving rise to a steeply inclined magnetic component in the core. Stepwise demagnetization of the samples by alternating field or thermal techniques is often necessary, therefore, to remove this component and isolate a stable primary magnetization vector or vectors.

Some workers have had success in separating different components of the magnetization and using these to orient cores. This approach assumes that the secondary, lower stability normal polarity component that can occasionally be identified in addition to the higher stability primary magnetization vector was acquired in the direction of the present-day Brunhes normal polarity period (i.e., in the past 0.73 m.y.). Differences between the declinations of the two components may be attributed to tectonic rotations. Shibuya et al. (1991), for example, used such a technique on ODP Leg 124 core samples to postulate a 60° anticlockwise rotation for the Celebes Sea during the Oligocene. This technique is somewhat restricted in its application: it usually requires either that significant rotation has occurred or that the samples be of reversed polarity, so that the Brunhes overprint can be identified and separated out reliably; and, furthermore, that any drilling-related overprint is absent or has not obscured the Brunhes component.

In addition to the problem of remagnetization, the above methods of reorienting features contain inherent errors arising from secular variations of the Earth’s magnetic field. Such variations may be of considerable significance, on the order of ±15° in declination and inclination, particularly in those lithologies that have acquired their magnetic characteristics rapidly, such as lava flows. Typically, a period of about 10⁴ to 10⁷ yr is considered sufficient to average out secular variations (Tarling, 1983); thus, slowly deposited sediment samples are considered to give more reliable indications of north than rapidly deposited sediments or lava flows.

Most important of all for our purposes, the assumption that the primary magnetization vector of the sample (if only a single component is isolated) will point due north or south can hold only if no tectonic rotation of the sample is suspected (see below). Nevertheless, under favorable circumstances, orientation of core to magnetic north using paleomagnetic data can be a simple and inexpensive technique in, for example, relatively undisturbed sedimentary sections from which paleomagnetic measurements are already being made as a matter of routine (as with ODP).

**COMPARISON WITH WIRELINE LOGGING DATA**

A third approach, and one which makes the directly and remotely sensed methods of acquiring structural information, is to reorient cores by comparing them with downhole images obtained from modern specialty logging tools, such as the FMS and BHTV. Data from these tools, both of which are routinely used by ODP, can be processed to generate images of the borehole wall, from small-scale variations in, respectively, resistivity and acoustic backscattering (Ekstrom et al., 1987; Zemanek et al., 1970). The resolution of the BHTV is estimated to be on the order of 3 mm in a 40-cm-diameter hole (Zemanek et al., 1970), and that for the FMS, 2.5 to 5 mm, although considerably finer features can be sensed by the latter if they have a sufficiently high-resistivity contrast (Ekstrom et al., 1987; Serra, 1989).

Both tools carry triaxial fluxgate magnetometers, so that the borehole images may be oriented to geographic coordinates, provided that
Measurement of Planar Features in Cores

Several methods of measuring planar features in cores are in use. The most accurate and sophisticated way is to use a goniometer, either mechanical (e.g., Nelson et al., 1987) or electronic (Bergosh et al., 1985). Nelson et al. (1987) claim a reproducibility error of ±2.75° in azimuth and ±0.75° in dip for the mechanical instrument, and about half of that with the electronic device.

An alternative technique, less precise but usable when no specialized equipment is available, is to measure the features by hand by combining apparent dip measurements. This technique has been used successfully on many occasions with ODP cores (e.g., Taira, Hill, Firth, et al., 1991; Parson, Hawkins, Allan, et al., 1992; Gillis, Mével, Allan, et al., 1993), but it is equally applicable to any core. ODP cores, which are recovered in plastic liners, are routinely sectioned along the axis of the core. One half of the sectioned core is reserved for archiving, and the other is used for sampling purposes. The plastic core liners have orientation marks, and a nominal “core liner north,” which has no geographic significance, is chosen relative to these marks. Usually this “north” is taken to lie in the working half of the core, perpendicular to the plane along which the core was split (Fig. 1). Standard procedure is initially to make all structural and paleomagnetic measurements relative to these synthetic coordinates, before any attempt to reorient them to geographical coordinates. Note that, although most sections of soft un lithified sediment recovered by hydraulic piston coring techniques should be contiguous within any one core barrel, in those more lithified formations recovered by rotary coring, in which recovery is usually much less than 100%, the core is broken up by the drilling process and each individual piece is rotated independently of its neighbors. Consequently, pieces will have randomly oriented true azimuths.

In un lithified sediments, dips and strikes of bedding are made by the measurement of two apparent dips: one on the cut (“east-west”) surface of the core, and another on a surface perpendicular to this, made by removing a quarter round of core using a scoop or some such apparatus (Fig. 2). With a moderate amount of practice these measurements can easily be made to the nearest degree. The two apparent dips are combined into one dip and strike (relative to the synthetic coordinates) using simple stereographic techniques. Significant errors in the strike measurement in near-horizontal bedding are to be expected by this method, but these decrease rapidly as the dip increases (Fig. 3). Dip estimates are much more well constrained and should be no worse than ±1° to ±2°. In many cases planar features lie at the ends of core pieces, in which case their dips and strikes can be measured directly.

In lithified but coherent cores, synthetic orientations can be measured according to a similar principle, by sawing the core to obtain the second apparent dip surface. Often a horizontal surface may be cut and a strike measurement obtained instead or as well, and this con-
strains much better the orientation of the feature: the estimated uncertainty in strike azimuth being reduced to no more than ±1° to 2°.

Measurement of Planar Features on FMS and BHTV Images

The FMS and BHTV carry triaxial fluxgate magnetometers that allow orientation of their resistivity and acoustic backscatter measurements respectively. The accuracy of the magnetometers is claimed to be in the order of ±2° (Schlumberger 1986), that is, better than the manual measurement of features in the core (Fig. 3), although the possibility of systematic errors in or adjacent to highly magnetic formations (e.g., oxide gabbros: Goldberg et al., 1992) should be noted.

Processed FMS and BHTV images are displayed on a rectangular plot that represents an unwrapped image of the inside of the borehole. The x-axis, equivalent in width to the circumference of the borehole, gives the azimuth of the image relative to true north, and the y-axis, the borehole depth. Inclined, planar features intersecting the borehole will appear as sinusoidal traces on plots (Fig. 4). Calculation of the orientations of planes is made simply by measuring the azimuth of the lowest point of the sinusoidal feature to obtain the dip direction, and working out the arctangent of the difference in height of the top and bottom of the trace (h) divided by the borehole diameter (d) (Fig. 4). Acetate overlays with sinusoids of known dip may be constructed for use with hard-copy images, but they are specific to given vertical and horizontal scales and borehole diameter. Software is now commonly in use that allows the matching of sinusoids interactively with computer-displayed images (e.g., the Schlumberger “FMS Image Examiner”: Serra, 1989; Bourke et al., 1989; or the “BHTV Image” interactive work station: Barton et al., 1990). Errors introduced at this stage of the process, particularly with the computer-picked sinusoids, are considered to be minimal.

The BHTV presents coverage of 100% of the borehole wall; in contrast, an FMS image from a single pass of the tool covers approximately 40% of the surface of the borehole only (for the ODP four-pad tool), depending upon the hole diameter. Whereas sinusoidal features can be observed unambiguously on BHTV images, on FMS plots they are discontinuous and must be interpolated between the individual pad traces. To minimize errors resulting from false correlations, two passes of the FMS tool are often made and their resistivity images merged into a single plot to increase the effective coverage of the borehole (although in practice the tool tends to follow the same path...
if the borehole is even slightly elliptical; see, for example, MacLeod and Pratt, this volume).

In addition to the manual picking of dips from FMS images, whether by hand or with a work station, FMS data from the four-pad tool can be processed to yield plots of bedding dip and strike analogous to those produced by the Dual Dipmeter (or Stratigraphic High Resolution Dipmeter) Tool. In essence, this processing involves the comparison and correlation of resistivity responses between the four pads over a given interval of the borehole. The resistivity response of a dipping feature with characteristic signature will be recorded by the pads at different depths, and from this its dip and strike can be calculated. A number of techniques for the computation of dips from the resistivity data are in use, based upon different methods of correlation between pads. The techniques, and interpretation of their results, are discussed in detail in Schlumberger (1986). However, it is pertinent to note that most of these methods (including the standard “Mean Square Dip” computation) involve calculation of a single “best fit” average dip measurement over a given search interval, typically 4 ft (1.2 m); therefore, it is most suitable for regular, planar-bedded sedimentary sequences. Fractures, veins, and smaller scale bedding features that may be visible in the core and on the FMS images are not likely to be discriminated by such computational techniques.

**Methodology of Core-log Integration**

If an inclined planar feature visible on FMS or BHTV images of an interval of borehole can also be recognized in core from the same interval, then that section of core can be reoriented to geographic coordinates. Not only are the inclined features reoriented (be they bedding, joint planes, or whatever), but also all other cryptic features within the same contiguous core piece that cannot be imaged by the logging tools, including fault slip lineations, microfabrics, paleomagnetism, and so forth. Systematic deviations of, for example, restored, cleaned paleomagnetic declinations away from north may be indicative of tectonic rotations about vertical or inclined axes (see below).

The principle of core reorientation is illustrated in Figure 5. It is demonstrated in practice in the example given below, based upon the following methodology. The core or core photographs are compared with the FMS records from the same interval. One 9.5-m core is a convenient length for the initial comparison. Distinctive lithologic features (e.g., turbidite horizons or groups of horizons) may allow beds to be matched directly on a 1:1 basis with the equivalent resistivity variations on the FMS records. In most instances recovery is less than complete, in which case the depth of the feature in the core and the equivalent horizon on the logs will not be identical, and a correction will need to be made. In this regard it is useful to distinguish “core depth” from “log depth.”

It is not usually possible to correlate many pieces of core with the FMS on a 1:1 basis. More often, a core piece may only be constrained to lie within a particular depth interval. If no definite matches have been made then the size of this window will depend upon the amount of core that is missing and the position of the particular core piece within the recovered material.

Bedding orientations are obtained both from the automatic “dipmeter” processing of the FMS resistivity data, and from horizons picked manually from the FMS images using log analysis software. Use of the latter allows faults and fractures to be recognized and measured in addition to the sedimentary bedding; furthermore, it enables individual bedding planes to be measured, rather than the average bedding orientation per unit interval that is obtained from the dipmeter computation.

Magnetization directions of discrete samples of core are oriented relative to core-liner coordinates. Bedding and/or fracture planes from the same contiguous core piece are measured relative to the same coordinates. These planes are then compared with FMS bedding and fault orientations taken from the window of possible log depths.

Figure 5. A. Sedimentary bedding measured from the core (Figs. 1-2), together with the cleaned stable remanent magnetization vector from a sample from that same contiguous core piece, are plotted relative to core liner coordinates (lower hemisphere, equal-angle projection). B. The true sedimentary bedding dip and dip direction are known from FMS or BHTV images from the same interval. C. The core bedding is rotated, therefore, to the true bedding orientation and the sample magnetization vector is rotated by the same amount. The deviation of the restored magnetization vector from north (or from south if the sample is of reversed polarity) may be the result of a tectonic rotation.
In most cases, several FMS bedding measurements are taken from the relevant depth interval (which will typically be a few meters). Ideally, the bedding orientations will be consistent, and consequently there will be no ambiguity as to an appropriate dip direction to use for reorientation of the core bedding. If the FMS data show a range of dip directions, then strict criteria must be applied to choose the most appropriate direction to use. If fractures have been measured in the core and with the FMS work station, then the angular relationship between bedding and cross-cutting fractures provides powerful constraint on the most appropriate dip direction to use; indeed, it is often more appropriate to reorient a piece of core relative to a fracture set or set of fractures than to sedimentary bedding. Stereographic projections of the bedding and fault data (relative to core-liner coordinates) from each contiguous core piece and of the relevant FMS data (relative to true north) can be compared to aid the reorientation process. Dip magnitudes as well as directions are also considered; those dip picks that differ greatly from the core bedding dip are deemed to be inappropriate and are discarded. In those intervals of the borehole most obviously affected by faulting, we have found the dips made by the automatic dipmeter to be less consistent than those picked by hand from the FMS work station; in such instances the latter were generally preferred.

If the spread of dip orientations that meet the above criteria is small, then the core measurements are restored to the most representative FMS dip reading. If, however, the FMS dip direction data from the relevant interval are still inconsistent, and fault data do not allow a unique direction to be constrained, no unique solution can be determined. In this case none is chosen and the core piece is therefore not reoriented.

In practice, definite correlations between inclined features in core and on log images may only be possible at certain intervals within the borehole. This does not necessarily restrict the usefulness of the technique; in determining the magnitude and timing of tectonic rotations, for example, it is better to obtain accurately restored magnetic declinations from fewer discrete, well-constrained intervals in the borehole than to attempt to make correlations of dubious reliability from the entire depth range. The principal uncertainty in the technique is likely to be in making inappropriate matches between features in the core and on FMS or BHTV logs; thus, as large a number of reorientations as possible should be made from the better constrained intervals (typically regular, parallel sedimentary bedding over a depth range of several meters to tens of meters) to minimize spurious matches.

A computer program has recently been developed for the KTB drilling project to aid the correlation of features between core and logs (Kessels and Küch, 1992). It uses a similar methodology to that outlined here, matching the dip, azimuth, and relative depth of each feature in any one core piece against features within a given search interval on the borehole image. It places the core features in every possible position, calculates the mismatch of the three parameters in each case, and takes as its preferred solution the depth and orientation with the minimum residual error. With their program, the authors claim a mean standard deviation for the restored azimuths of ±2° with respect to the best results obtained using manual reorientation techniques.

The declination errors inherent in the manual reorientation technique described herein are estimated to be typically on the order of ±8° to 12° (at 2 standard deviations) for hand-measured dips (depending on whether a dip and a strike or two apparent dips are used to define the core measurement; the stated figure is for a plane dipping at 15°), or ±7° to 8° using an electronic goniometer. These figures assume an uncertainty of ±2° in the FMS/BHTV magnetometer measurement, and ±3° in the paleomagnetic measurement. For further discussion of the most appropriate statistical treatment of the errors involved, see Sager et al. (this volume).

The method of core orientation described herein is not restricted to use with DODP but can potentially be applied to any core for which logging data are available, and at any stage; for example, if the need for obtaining oriented material was not appreciated at the time drilling took place, and a multishot tool was therefore not employed or not available. It is also an extremely inexpensive means of acquiring oriented core when compared with the operating costs of either the camera-based or electronic multishot tools, and it does not suffer the disadvantage of the older style multishot orientation tool of being restricted in use to soft sediment.

**EXAMPLE**

The Lau Basin is a triangular-shaped, active, backarc marginal basin in the southwestern Pacific, forming at the leading edge of the Indo-Australian Plate as it overrides the subducting Pacific Plate (Fig. 6A). The basin lies between a north-trending remnant arc (the Lau Ridge) to the west and a north-northeast-trending active island arc/forearc complex (the Tonga Ridge) in the east (Fig. 6B). It is clear that the extent of opening of the basin has been greater in the north-central part than in the south, and various models have been proposed that involve rifting and translation of the active and remnant arcs during basin formation: either of the Lau Ridge away from the (essentially static) Tonga Ridge (Packham, 1978; Herzer and Exon, 1985) or vice versa (Kang, 1970; Hawkins et al., 1984). All of these hypotheses require the bulk rotation of either one or both of the Lau and Tonga ridges as the Lau Basin opened.

We now think, following the ODP drilling (Parson, Hawkins, Allan, et al., 1992; and see papers in this volume), that the opening history of the basin involved a protracted period of attenuation and rifting of the original Lau/Tonga protoarc before initiation of the backarc seafloor spreading known to be active at the present day (e.g., Collier and Sinha, 1990; Parson et al., 1990). Parson and Hawkins (this volume) suggest that the backarc spreading axis (now represented by the Eastern Lau Spreading Center) formed at approximately 5.5 Ma in the vicinity of the Peggy Ridge and propagated southward through the attenuated arc crust, "unzipping" the Lau and Tonga ridges as it did so. This arc rifting process is continuing today at the Vula Fa Ridge. In the past 1 to 2 m.y., a second propagating rift (the Central Lau Spreading Center) has formed and is moving rapidly southward through the existing backarc crust, at the expense of the Eastern Lau Spreading Center (Parson et al., 1990; Parson and Hawkins, this volume).

Leg 135 drilled six sites in the western part of the Lau Basin, between the Lau Ridge and the active Lau spreading centers, and two on the Tonga platform/forearc (Fig. 6B). The latter two sites were of particular interest with regard to the above debate; specifically, to attempt to determine whether or not the Tonga Ridge had rotated clockwise during opening of the Lau Basin. Site 841 was drilled in approximately 4800 m of water on the upper trench slope of the Tonga forearc, through late Eocene to Holocene turbidites and oozes into a low-K rhyolitic arc complex (Parson, Hawkins, Allan, et al., 1992). Seismic reflection data indicate recent faulting in this part of the forearc, and Site 841 is the sole site drilled during Leg 135 at which we have evidence for significant faulting and disruption of the succession. Tilting of the sediments, even close to seafloor, has been such that dips in excess of 30° are not uncommon (MacLeod, this volume). This tectonic tilting makes the site ideal for application of the reorientation technique described herein, both to reorient the paleomagnetic measurements (to address the broader scale tectonic questions outlined above) and the hundreds of small-scale structures and veins measured from the core. The relatively steep dip to many of the sedimentary strata minimizes those errors because of the manual measurement of core dips (cf. Fig. 3).

In Table 1 we present a subset of the raw bedding and magnetic data from Hole 841B, together with the FMS dip picks from the corresponding intervals of Hole 841C, to illustrate how the reoriented data are derived. In total, 120 cleaned paleomagnetic data and 127 faults have been reoriented using the method described herein (Figs. 7-8). These data are discussed in detail by Sager et al. (this volume) and MacLeod (this volume), respectively.

The paleomagnetic data plotted in Figure 7 have not been corrected for bedding dip. Application of conventional bedding correc-
do not place much emphasis on the slightly more N-S strike of the faults. Hence, valuable information is gained by reorienting structural data to obtain kinematic information from faults detected by the FMS; reoriented following the procedure described for the paleomagnetic coordinates (Sites 834-839; Fig. 6B), which exhibit consistent northerly orientations in dip between the shallowly dipping reverse faults and NE-SW normal faults. The structural implications of the fault data are discussed in detail by MacLeod (this volume).

**DISCUSSION**

The lack of orientation information is a serious handicap to many different studies of borehole cores, and hinders the integration of core data with broader scale geological information obtained from other sources. Although specialist core orientation tools exist, they are expensive to operate and tend to be unreliable. Other reorientation techniques have serious flaws that restrict their usefulness. We have shown here, however, that it is not only possible but practical to reorient cores to an acceptable degree of accuracy by comparing planar features in the cores with their representations on FMS and BHTV downhole images.

Applications of this technique are many. Particularly valuable is the ability to detect tectonic rotations from anomalies in restored paleomagnetic declinations. Land-based paleomagnetic studies have shown that tectonic rotations on a variety of scales are a integral part of the deformation process in continental tectonic belts (e.g., Kessel and Laj, 1989, and papers therein). It is clear that such rotations do not only occur on land, nor are they restricted to continental crust: structural and paleomagnetic studies of ophiolites, for example, have shown that ocean-floor rotations about subhorizontal, subvertical, or oblique axes are common in many tectonic environments (e.g., Allerton and Vine, 1987; Bothhomm et al., 1988). Nevertheless, although vertical axis rotations have been postulated from analyses of magnetic lineations (e.g., Tamaki and Larson, 1988; Searle et al., 1989) and seamount magnetic anomalies (Sager and Pringle, 1987), they have largely been inferred by indirect means only. This is mostly for practical reasons, principally because of the difficulty of recovery and orientation of samples from the seafloor.

The technique outlined here offers one of the first direct means of detecting vertical axis tectonic rotations (or components of rotation) in the oceanic domain. This should, in turn, allow better understanding
Figure 6. A. Location of the Lau backarc basin. The shaded areas have bathymetries of <2000 m, and land is shown in black. Active subduction zones are marked with black barbs; inactive subduction zones with white barbs. The area of Figure 6B is shown by the box at upper right. B. Detail of the Lau Basin area. The locations of sites drilled on Leg 135 are indicated, together with DSDP Site 203. The data considered in this paper come from Site 841, on the upper trench slope of the Tonga forearc. CLSC = Central Lau Spreading Center, and ELSC = Eastern Lau Spreading Center.
Figure 7. Restored magnetic vectors from Hole 841B core data. A. Equal area stereographic projection. Note the approximately antipodal directions of reversed polarity samples (lower hemisphere) with respect to normal polarity samples (upper hemisphere). B. Rose diagram of restored declinations, with reverse polarity samples projected through the origin and plotted as if of normal polarity. The restored data show a clear deviation away from the present-day Earth's field direction, and we postulate that this is the consequence of a clockwise rotation of the Tonga Ridge upon opening of the Lau Basin. See text for discussion. \( N \) = number of samples.

ACKNOWLEDGMENTS

We would like to thank F.J. Vine and C.J. Evans for their careful reviews, and R.B. Whitmarsh and B.J. Murton for comments on an earlier version of this manuscript; M. Rees and N. Brown of Sperry-Sun Drilling Services in Aberdeen, and M. Storms of ODP, for unpublished information and useful discussions on the merits of the modern electronic multishot devices; N. Abrahamsen, for performing some of the sample demagnetizations, and R. Reynolds for processing the FMS data during Leg 135.

REFERENCES

Abbreviations for names of organizations and publication titles in ODP reference lists follow the style given in Chemical Abstracts Service Source Index (published by American Chemical Society).

Figure 8. Restored faults from Hole 841B core data. A. Rose diagram of the strikes of normal fault planes. B. Contoured lower hemisphere equal area projections of poles to normal fault planes. C. Rose diagram of the strikes of reverse fault planes. D. Contoured lower hemisphere equal-area projections of poles to reverse fault planes. Note the preferred trend parallel to the strike of the Tonga Trench (Fig. 6B), and the significantly shallower dip of the reverse faults than the normal faults. The tectonic implications of the data are discussed by MacLeod (this volume). \( N = \) number of samples.
