35. GEOTECHNICAL PROPERTIES AND CONSOLIDATION CHARACTERISTICS OF NORTH PACIFIC SEDIMENTS, SITES 881, 883, AND 885/886

Anne K. Rutledge, John A. Roberts, Thomas H. Orsi, William R. Bryant, and Aarno T. Kotilainen

ABSTRACT

Consolidation tests performed on samples representative of the major sediment types recovered during Ocean Drilling Program Leg 145 indicate that the diatom oozes and clays of Sites 881, 883, and 885/886 may be characterized as normally consolidated, moderately to highly compressible, and slightly permeable to impermeable. Comparison of field and laboratory consolidation curves reveals a disparity between porosity variations caused by loading (i.e., burial) observed in situ and under laboratory conditions. The field consolidation curves indicate that the high porosities characteristic of diatomaceous oozes are preserved in spite of the increasing sediment load, most likely the result of a resistance to consolidation due to the structural strength of the diatom frustules, whereas the laboratory consolidation curves (e-Log p) reveal a reduction of porosity with increasing load as expected. Use of the empirical relationship between the ratio of undrained shear strength to effective overburden stress and the state-of-consolidation for a sediment supports both stratigraphic and gamma-ray attenuation porosity evaluator (GRAPE) correlation data, suggesting an erosional unconformity in the upper 20 mbsf of Hole 885A. A medical CT (or CAT) scanner was found to be useful in evaluating the suitability of samples selected for consolidation testing. With increased availability, this device could conceivably replace, or at least provide a valuable supplement to, X-rayradiography for the nondestructive three-dimensional examination of whole core samples.

INTRODUCTION

The application of geotechnical testing methods to marine sediments by geoscientists has become a widely accepted practice over the past 20 years. These techniques supplement the more common sedimentological analyses (e.g., textural and mineralogical analyses, particle identification, and sedimentary structure analyses) used to enhance our understanding of the dominant geologic processes (Bryant et al., 1974, 1981; Keller, 1974; Bennett and Nelson, 1983; Pittenger et al., 1989; Bryant and Rack, 1990). Standard Ocean Drilling Program (ODP) shipboard physical property measurements include the index properties (water content, wet and dry bulk density, GRAPE bulk density, grain density, void ratio, and porosity), sediment shear strength, and compressional-wave velocity. These data are essential as input for acoustic models of the seafloor and sediment mass-accumulation calculations. Sediment index properties are closely linked to the sedimentological processes that have acted upon the sediment. Realization that downhole variations in physical properties often reflect even minor lithologic changes, in addition to the physical state of the sediment, has led to use of these data as a stratigraphic tool (Taylor, 1984; Pittenger, 1992). Shear strength, for example, is a function of mineralogy, grain size, particle type, water content, diagenesis, depth of burial, and stress history. Consequently, information regarding shear strength variation with increasing depth below the seafloor can contribute to our understanding of the postdepositional processes affecting marine sediments. In addition to the shipboard physical property analyses, consolidation testing is used by marine geologists to gain insight into a sediment’s stress history and to determine the magnitude and timing of the porosity and permeability changes induced by the addition or removal of overburden by sedimentary processes.

The primary objective of Leg 145 was to improve our knowledge of the paleoceanography and paleoclimatology of the North Pacific Ocean. The sites selected to meet this objective also presented us an opportunity to expand upon the study of the geotechnical properties and consolidation characteristics of the North Pacific sediments begun on Deep Sea Drilling Project (DSDP) Leg 86. The purpose of this study is to examine the extensive set of physical property data from Sites 881, 883, and 885/886 and to augment these data with consolidation and permeability test results.

METHODS

Shipboard Physical Properties

The shipboard physical properties measurements made during Leg 145 were performed using standard ODP methods as detailed in Boyce (1976) and the “Explanatory Notes” chapter in the Leg 145 Initial Reports volume (Rea, Basov, Janecek, Palmer-Julson, et al., 1993). Summaries of the shipboard physical properties results for Sites 881, 883, and 885/886 may be found in their respective chapters in Rea, Basov, Janecek, Palmer-Julson, et al. (1993). The sampling strategy used for these sites was designed to maximize the physical property sampling resolution within the time constraints imposed by shipboard operations. Index property, compressional-wave velocity, and shear strength measurements were made two per section in cores from Holes 881B and 883A, one per section in cores from Holes 881C, 883C, 885A, 886A, 886B, and 886C and Cores 145-883B-1H and -3H through -86X, and one per every two sections in cores from Hole 881D.

A continuous record of wet bulk density was generated for all of the cores from Sites 881, 883, and 885/886 using the gamma-ray attenuation porosity evaluator (GRAPE) on the multisensor track (MST). Bulk density is calculated from gamma-ray attenuation using the relationship (Evans, 1965):
of these analyses are presented in Table 1. Uniaxial consolidation tests
Before plotting, the GRAPE data were smoothed using a 29-point
algorithm used to calculate bulk density from gamma-ray attenuation
where:
\[ \rho_b = \left( \frac{1}{\mu} \right) \ln \left( \frac{I_0}{I} \right), \]

Mass Attenuation Coefficient

Using this relationship to calculate density sampling assumes that the
mass attenuation coefficient of quartz is an acceptable estimation for
the actual mass attenuation coefficient of the sediment. Bulk density
values obtained in this manner are approximately 10% higher than
those obtained using volumetric techniques. Boyce (1976) attributed
this discrepancy to the ~10% difference in the Compton mass
attenuation coefficients of water and quartz. High-porosity sediments,
such as the diatom oozes characteristic of the North Pacific, are particularly
subject to this type of error. The 0.1 g/cm\(^3\) offset between the GRAPE
data and the discrete measurements reported in the Initial Reports
volume (Rea, Basov, Janecek, Palmer-Julson, et al., 1993) results
largely from the inadvertent omission of this correction from the
algorithm used to calculate bulk density from gamma-ray attenuation
(Moran, 1993). The GRAPE data presented here have been corrected
for this offset using the Boyce equation (Boyce, 1976):
\[ \rho_b = \left( \frac{\rho_{bc} - \rho_{bc}}{\rho_{bc} - \rho} \right) + \rho_f, \]

where:
- \( \rho_b \) = bulk density
- \( \rho_{bc} \) = calculated bulk density (using mquartz)
- \( \rho_f \) = true fluid density
- \( \rho_{bc} \) = calculated fluid density (using mquartz)
- \( \rho_g \) = true grain density,
- \( \rho_{gc} \) = calculated grain density (using mquartz)

Before plotting, the GRAPE data were smoothed using a 29-point
running average to improve the legibility of the plots while reducing
the resolution as little as possible.

Consolidation Testing

All consolidation test samples were subsampled for percent sand-
silt-clay analyses. The grain-size analyses followed standard sieve
and pipette analysis techniques as set forth in Folk (1974). The results
of these analyses are presented in Table 1. Uniaxial consolidation tests
and falling-head permeability measurements were performed at the

Consolidation samples from Sites 881, 883, and 885/886.

Texas A&M University (TAMU) Department of Civil Engineering
Soil Mechanics Laboratory using standard Soiltest load frames and
fixed-ring oedometers. Twelve samples (6.38 cm diameter × 2.54 cm
height) were loaded incrementally to 800 kPa, unloaded to 50 kPa,
then reloaded to a maximum of 3200 kPa on a 24-hr loading schedule.
Time-compression curves were produced for each load using the techniques
discussed in Head (1988). The void ratio at 24-hr (e24)
coefficient of consolidation (c\(_c\)), coefficient of volume compressibility
(\(m\)), and the permeability (k) were calculated based on the data
contained in the time-compression curves. At the end of each test,
plots of void ratio vs. the logarithm of the effective stress (e-Log \(P^e\))
were generated. The preconsolidation (\(P^c\)) stress of each consolidation
sample was determined from the e-Log \(P^e\) plot using the Casagrande
technique (Casagrande, 1936). The overconsolidation ratio
(OCR), defined as the ratio of the preconsolidation stress to the existing
effective overburden (\(P^c\)), provides insight into the stress history
of the area and can reveal the presence of erosional or nondepositional
hiatuses that are otherwise undetectable. By determining the degree
of consolidation, we can estimate the amount of overburden removed
in the case of overconsolidated sediments, and detect areas subject to
rapid sedimentation or excess pore pressures in the case of undercon-
solidated sediments. A thorough discussion of the limitations of the
Casagrande technique as applied to marine sediments may be found
in Bryant and Rack (1990). Plots of the ratio of undrained shear
strength to effective overburden stress (\(S^u/P^e\)) vs. depth have been
generated to supplement the state-of-consolidation data obtained from
the uniaxial consolidation tests (Skempton, 1970). In general, the
permeability values calculated from the \(c\) for each load applied during
the test are indicative of the magnitude of change in permeability
that occurred as a result of burial.

CT Scan Examination

Terzaghi’s (1943) theory of consolidation is based on a number of
assumptions, one of which is sample homogeneity. The possible effects
of inhomogeneities on test results are many. Gravel or shells, for
instance, can produce anomalously low compressibility, whereas
usually high compressibility and permeability could result from open
burrows or cracks. Furthermore, the quality of consolidation test
results are strongly influenced by sample quality. As a result, the ability
to assess the degree of sample disturbance prior to testing is highly
desirable. Worst case in these scenarios is an invalidation of test results.
Verifying the homogeneity of a consolidation sample is difficult
and accomplished mainly through visual inspection. Unfortunately,
structures may be internal or so subtle they remain invisible to the
unaided eye. X-radiography has long been used to examine whole
round samples, but superimposing three-dimensional structures onto
two-dimensional photographic film complicates interpretation. In a
different approach, we used X-ray computed tomography (CT or CAT scanning) to evaluate the internal structure of consolidation samples from Hole 886C. The technique is fast, quantitative, and extremely sensitive to subtle density contrasts. Moreover, visualizing internal structures (if present) may help evaluate the consolidation test results.

The technique uses a second-generation translate-rotate brain scanner (Vinegar and Wellington, 1987). The sample is centered within a circular gantry supporting the X-ray source and detectors. Rotating about the test sample, each source-receiver location provides a line integral measurement of X-ray attenuation called a ray sum. After measuring and combining over a span of locations greater than 180°, transformation of the ray sums by a filtered back-projection reconstruction algorithm results in a two-dimensional grid of X-ray attenuation values (Brooks and Dí Chiro, 1975). The density of the material is the predominant factor determining X-ray attenuation at the energies of 120 kV used for most medical scanners (McCullough, 1975). CT scanners convert X-ray attenuation to a parameter called the Hounsfield unit (HU) by normalizing it to the attenuation coefficient of water, and linearize the scale by arbitrarily assigning HU = -1000 to a value of 0 and HU = 1000 to HU = 0. (The Hounsfield unit is named after G.N. Hounsfield, the Nobel prize-winning inventor of the CT scanner; Hounsfield, 1973).

The scanner has an automatic micropositioning table to move the sample in and out of the image plane with a precision of about 60 μm. The sediment core was positioned horizontally and fixed to the CT scanner positioning table in the center of the imaging plane. A slice thickness of 7 mm full width, half maximum (FWHM) and an in-plane resolution of 0.4 mm were used for the samples in this study. All images were acquired at 120 kV/25 mAs for the sample position was moved incrementally through the image plane at 7-mm steps. The resulting nonoverlapping images are aligned perpendicular to the cylindrical axis of each core. Each reconstructed CT data file is a 256 × 256 numerical array that was downloaded from magnetic tape for analysis on a Macintosh II computer using Spyglass Transform visualization software.

RESULTS

Shipboard Physical Properties

A complete set of the shipboard physical property results may be found in Rea, Basov, Janecek, Palmer-Julson, et al. (1993). Profiles of sediment shear strength, wet and dry bulk density, water content, and porosity for Holes 881C, 883B, 883C, and 886C are presented in Figures 1–8. In general, the profiles exhibit the types of changes expected with increasing depth: decreasing water content, porosity, and void ratio values and increasing shear strength and density. The properties correlate well with lithologic variations, and a comparison of the index property profiles with the lithologic units (Shipboard Scientific Party, 1993a, 1993b, 1993c) shows that strong inflection points on the profiles occur at major lithologic boundaries. Variations in porosity and water content characteristic of the diatom oozes are shown in Figure 5. The organic content increases near the water interface in this zone. As a result, inferences regarding state-of-consolidation with depth presented in Figure 9 may be used to infer variations in the relative state-of-consolidation with depth (Skempton, 1970). Sediments with S0/S1' values that fall within the crosshatched region (0 < S0/S1' < 0.5) are normally consolidated whereas sediments with values less than 0.2 are underconsolidated and greater than 0.5 are characteristic of overconsolidated sediments. The profiles for Holes 886B and 886C are typically of normally consolidated marine sediments. The upper 10 mbsf of the section in all three holes seems to be overconsolidated. However, this apparent overconsolidation of the uppermost portion of the sediment column is actually a reflection of the disparity between the magnitude of the intrinsic shear strength, due to cohesion in the case of clays or to the interlocking of particles in the case of biogenic ooze, sands, or silts, and the low effective overburden stress (zero at the sediment/water interface) in this zone. As a result, inferences regarding state-of-consolidation in the upper several meters of the sediment column based on S0/S1' vs. depth profile must be made with caution. The S0/S1' profile for Hole 885A reveals two zones of overconsolidated sediment, one from 13 to 17 mbsf and another from 20 to 51 mbsf. Figure 10 presents a correlation of the GRAPE records from Holes 885A, 886B, and 886C and a composite section (see Dickens et al., this volume). Lines on the figure show the correlation. A missing section occurs at approximately 19–20 mbsf in Hole 885A. A comparison of the radiolarian biostratigraphy in Holes 885A and 886C suggests a missing section in Hole 885A at approximately 13 mbsf (J.I. Morley, pers. comm., 1994). The overconsolidated nature of the sediment below 13 mbsf suggests that a hiatus at this depth is the result of an erosional episode. Unfortunately, the lack of consolidation test data for Hole 885A precludes further substantiation of the proposed erosional event and assessment of the amount of overburden removed.

Consolidation Testing

Six samples from Hole 886C, three samples from Hole 881C, and three samples from Hole 883B were selected for consolidation testing. Each of these samples was selected to represent the suite of sediments recovered during Leg 145. Sediment types include spicule clay, diatom ooze with clay, diatom ooze, clay, red clay, clayey diatom ooze, and clay with diatoms. The results of the consolidation tests are summarized in Table 2. Additional consolidation test results from the upper section of Hole 883B are presented in Roberts et al. (this volume). OCR values for all of the tests fall within the range of normally consolidated to slightly overconsolidated. Values for c_v and m_v are reported for loads approximating the in situ effective overburden. All of the consolidation samples had high to very high initial void ratios (e_0 = 1.8 to 4.1), which contribute to the medium-to-high-volume compressibility values (m_v = 0.13 to 2.22 m^2/MN) observed. The c_v values reported are typical of low plasticity clays or silts except for the values for the Unit III clay from Hole 886C which had c_v values characteristic of a medium plasticity clay. The permeability values calculated from the c_v data range from a high of 10^-3 m/s for diatom-rich sediment to a low of 10^-10 m/s for the red clay sample. The calculated values are significantly (two orders of magnitude) lower than values obtained from the falling-head permeability test. This result is contrary to expectations based on the high initial

compaction seen in the time-compression curves. Time-compression curves of this nature are characteristic of partly saturated sediments that would be expected to exhibit low measured permeability as a result of air impeding flow through the pores. Taylor (1984) suggested that high falling-head permeability values might be an artifact of an increased drainage rate due to seepage-induced consolidation. Pittenger et al. (1989) reported permeability results with a single order of magnitude difference between calculated and measured values for diatom oozes of the Voring Plateau. Pittenger's findings suggest that permeability results of this nature are characteristic of sediments with a biogenic silica component. We think that a leak in the oedometer is the most likely explanation for our anomalous values.
Figure 3. Wet bulk density, GRAPE density, dry bulk density, and grain density profiles for Holes 883B.
The $e$-$\log P'$ curves for the tests conducted during this study are typical of marine sediments (Figs. 11, 12). The high initial void ratios may be attributed to the high percentage of diatoms present in all of the samples except for the three clays (Shipboard Scientific Party, 1993a, 1993b, 1993c). It is interesting to note the almost identical nature (curve shape and range of void ratio values) of the $e$-$\log P'$ curves in Figures 11F and 12F. Based on this comparison, the samples might be assumed to be of similar sediment types with similar stress histories. They are, in fact, very different. The curve in Figure 11F is for a clay recovered from a depth of 71.2 mbsf, whereas the sample represented in Figure 12F is a diatom ooze (80% diatoms) with clay and calcite recovered from a depth of 456.1 mbsf. This suggests that sediments

with a significant diatom component do not experience the magnitude volume change in situ that laboratory consolidation tests predict. Comparison of the field consolidation curves in Figure 13 with the $e$-Log $P'$ curves provides further confirmation of this observation. The bold vertical lines on the field curves mark the top of a diatom-rich interval. In every case the void ratio increases sharply at the contact between the diatom-rich interval and the overlying clay-rich interval. In Figures 13B and 13D, the vertical dashed lines mark the bottom of the diatom-rich interval. A rapid reduction of void ratio occurs below this point similar to that seen in laboratory consolidation tests. The porosity profiles (Figs. 2, 4, 6, 8) also support the premise that little in situ consolidation occurs in diatomaceous sedi-
low-density feature (2-cm diameter) that migrates with depth in the sample (i.e., its orientation is oblique to the scan plane and hence moves from right to left in sequential CT images). This feature is apparently some sort of feeding structure created by an animal larger than those producing the other burrows.

Although CT image sequences of samples of uniform composition without distinct sedimentary structures are somewhat monotonous, they provide verification of Terzaghi's (1943) assumption of sediment homogeneity. Although it might be tempting to ascribe the apparent lack of significant structure in these samples as a failure (or at least a weakness) of CT, previous calibration experiments conducted on the Technicare A-100 CT scanner found the density resolution (precision) of the machine to be ~0.005 mg/m$^3$ (Orsi, 1994; Orsi et al., 1994). This precision is identical to that achieved by Been (1981) for an X-ray apparatus developed to measure vertical bulk density distributions within laboratory sedimentation columns. As stated by Been (1981), “...greater precision is not warranted [in his or in the present investigation] as densities measured to the fourth significant figure fluctuate with temperature variations.”

CONCLUSIONS

The extensive set of physical property measurements made during Leg 145 provides further geotechnical characterization of the sediments of the North Pacific. This is particularly important in the case of the diatomaceous sediments recovered. Accurate interpretation of geotechnical test results depends upon the existence of a database comprising the accumulated results of previous tests for each type of sediment. The development of such a database for siliceous oozes has lagged behind that of other sediment types (i.e., terrigenous clays and calcareous oozes), but is progressing steadily. The results of this study should further serve to emphasize the need for continued study of the unique nature of diatomaceous sediments. The lack of in situ consolidation and the preservation of porosity of diatomaceous sediments has been demonstrated, although some question remains regarding the mechanism responsible for maintaining the downcore porosity. The $S_u/P_{o'}$ profiles for Holes 885A, 886B, and 886C, in conjunction with correlations of the index properties and radiolarian biostratigraphy, indicate the presence of a hiatus in the upper section of Hole 885A. The overconsolidated nature of the sediment points to an erosional nature for the hiatus. This technique is a quick and easy way to assess the state of consolidation of a sediment column, and is a valuable supplement to consolidation test data.

Wet bulk density is a fundamental property of marine sediments related directly to the sedimentation history of the deposit. Considering its sensitivity to this property, CT has a number of other potential uses besides that shown here. For example, it would be very useful to make strategic CT images indexed to other ODP measurements, such as GRAPE, magnetic susceptibility, velocity, etc., to achieve a better understanding of the depositional environment.
Figure 10. Correlation of GRAPE density profiles at Site 885/886. The arrow on the profile from Hole 885A marks the missing section.
understanding of physical property characteristics and sediment variability. In addition, sediment depth profiles of CT density can be generated by averaging values over a fixed region-of-interest within each CT image. These profiles are similar to those produced by the GRAPE system, although the “slab” of material integrated in CT differs from the cylindrical volume used for the GRAPE measurements. Importantly, the determination of the standard deviation of the CT image is crucial in studies of sediment heterogeneity.

ACKNOWLEDGMENTS

Our participation on Leg 145 was made possible by funding from USSAC (Rutledge, Orsi, and Bryant), ONR-NDSEG (Rutledge and Orsi), NERC and SERC (Roberts), and ESF (Kotilainen). We thank Dr. Wayne Dunlap for the use of the TAMU Department of Civil Engineering Consolidation Labs. Finally, we thank Dr. C.M. Edwards, Director of the Engineering Imaging Center of the Texas Engineering...
Experiment Station, for his helpful suggestions during the CT portion of this study.
