1. **LEG 189 SUMMARY**¹

Shipboard Scientific Party²

---

**ABSTRACT**

The Cenozoic Era is unusual in its development of major ice sheets. Progressive high-latitude cooling during the Cenozoic eventually formed major ice sheets, initially on Antarctica and later in the Northern Hemisphere. In the early 1970s, a hypothesis was proposed that climatic cooling and an Antarctic cryosphere developed as the Antarctic Circumpolar Current progressively thermally isolated the Antarctic continent. This current resulted from the opening of the Tasmanian Gateway south of Tasmania during the Paleogene and the Drake Passage during the earliest Neogene.

The five Leg 189 drill sites, in 2463 to 3568 m water depths, tested, refined, and extended the above hypothesis, greatly improving understanding of Southern Ocean evolution and its relation with Antarctic climatic development. The relatively shallow region off Tasmania is one of the few places where well-preserved and almost-complete marine Cenozoic carbonate-rich sequences can be drilled in present-day latitudes of 40°–50°S and paleolatitudes of up to 70°S. The broad geological history of all the sites was comparable, although there are important differences among the three sites in the Indian Ocean and the two sites in the Pacific Ocean, as well as from north to south.

In all, 4539 m of core was recovered with an excellent overall recovery of 89%, with the deepest core hole penetrating 960 m beneath the seafloor. The entire sedimentary sequence cored is marine and contains a wealth of microfossil assemblages that record marine conditions from the Late Cretaceous (Maastrichtian) to the late Quaternary and dominantly terrestrially derived sediments until the earliest Oligocene. The drill sites are on submerged continental blocks extending as far as 600 km south of Tasmania. These continental blocks were at polar latitudes in the Late Cretaceous when Australia and Antarctica were still united, although rifts had developed as slow separation and northward move-

ment of Australia commenced. The record in the cores indicates that the Tasmanian land bridge, at polar latitudes, completely blocked the eastern end of the widening Australo-Antarctic Gulf, during both the slow-spreading phase and the fast-spreading phase (starting at 43 Ma), until the late Eocene. Drilling evidence, especially that from clay minerals, in conjunction with other geological and geophysical evidence, indicates that there were two major tectonic events in the Paleocene and Eocene. The first involved folding and uplift as the eastern and central blocks of the South Tasman Rise (STR) were jostled in the late Paleocene on the northern extension of the Balleny Fracture Zone. The second was uplift and erosion of the ridge of the Tasman Fracture Zone on the western STR, as strike-slip movement started between the western block of the STR and Antarctica in the middle Eocene.

Prior to the late Eocene, marine siliciclastic sediments, largely silty claystone, were deposited in a relatively warm sea on broad, shallow, tranquil shelves. Sediment supply was rapid and despite the rifting, drifting, and compaction, largely deltaic deposition kept up with subsidence. Calcareous and siliceous microfossils are sporadic, and dinocysts, spores, and pollen are ever present. The spores and pollen are compatible with this part of Antarctica being relatively warm with little ice throughout this time and supporting temperate rain forests with southern beeches and ferns—part of the Late Cretaceous to Eocene “Greenhouse” world. Differences in the Eocene claystones between east and west indicate that the eastern Australo-Antarctic Gulf was more poorly ventilated than the gradually widening Pacific Ocean with its western boundary current, the southerly flowing East Australian Current. Although currents from low latitudes warmed both sides of the land bridge, it was warmer in the Australo-Antarctic Gulf west of Tasmania.

In the late Eocene (37 Ma), the Tasmanian land bridge had separated from Antarctica, the bridge and its broad shelves began to subside, and cool surface currents started to circulate around Antarctica from the west. These swept the still-shallow offshore areas, and glauconitic siltstones were deposited very slowly as condensed sequences. Palynological and other evidence suggests that there were considerable fluctuations in temperature superimposed on a general cooling and that the amount of upwelling also fluctuated in response to the changing oceanic circulation. Calcareous microfossils are rare, but benthic foraminifers indicate that some sites began to deepen slightly during the latest Eocene (34 Ma).

By the early Oligocene, warm currents from the tropics were cut off from some parts of Antarctica by the developing Antarctic Circumpolar Current, leading to cooling and some ice-sheet formation. These events contributed to global cooling. Conditions were significantly cooler in the Tasmanian offshore region, and there is no positive evidence of land vegetation in the sediments, although vegetation existed on Tasmania. However, organic matter deposited in the early Oligocene could have been oxidized during deposition in well-ventilated waters. Much of the land bridge had subsided beneath the ocean, so there was a smaller hinterland to supply sediment. Furthermore, the colder ocean provided less moisture and, hence, decreasing precipitation and erosion. Altogether, far less siliciclastic sediment was transported from the land and generally slow deposition of deep-water pelagic sediments was initiated. However, the East Australian Current and currents moving down the western Australian margin continued to keep the Tasmanian region relatively warm, resulting in carbonate deposition rather than
the siliceous biogenic deposition that marks much of the Antarctic margin. Furthermore, in the Tasmanian region, and even in the Cape Adare region on the conjugate Antarctic margin, there is no sign of glaciation during the early Oligocene.

The Drake Passage opened early in the Neogene, and the Tasmanian Seaway continued to open, strengthening and widening the Antarctic Circumpolar Current and strongly isolating Antarctica from warm-water influences from lower latitudes. At ~15 Ma, the east Antarctic cryosphere evolved into ice sheets comparable to those of present day. This intensified global cooling and thermohaline circulation. The “Icehouse” world had arrived. However, temperatures and current activity fluctuated, and dissolution and erosion varied over time. The Tasmanian region had been moving steadily northward so that its sediments were never south of the Polar Front, and pelagic carbonate continued to accumulate in deep waters at average rates of 1–2 cm/k.y. The upper Neogene sequences contain windblown dust from Australia, which was moving progressively northward into the drier midlatitudes. Along with the global climate change associated with high-latitude ice-sheet expansion, this led to massive aridity of Australia and an increase in dust abundance in some sequences after 5 Ma.

Comparisons with sequences drilled elsewhere on the Antarctic margin will further improve our understanding of these momentous changes in Earth history and some of the constraints on modern climates. If Australia had not broken away from Antarctica and moved northward, global climate may well have remained warm. We can now document in some detail the changes related to that tectonic movement. Tectonic information indicates that there were three critical tectonic events during the Cenozoic in the Tasmanian region: Paleocene strike-slip movement, terminating at 55 Ma by seafloor spreading south of the STR; Eocene strike-slip movement along the western boundary between the STR and Antarctica, terminating in the latest Eocene around 34 Ma; and early Oligocene subsidence of the STR and collapse of the continental margin around Tasmania. The early Oligocene subsidence and collapse also occurred in the Victoria Land Basin east of the rising Transantarctic Mountains (Cape Roberts Scientific Team, 2000) and along the Otway coast on mainland Australia, northwest of Tasmania.

Postcruise studies and comparisons will better define and explain regional similarities and differences in tectonism, sedimentation, and climate. Initial studies of physical properties, wireline logs, and microfossils all show that climatic cycles of varying length are present throughout the entire sequence, and postcruise studies will better define Milankovitch-scale and other cycles. In the Neogene pelagic carbonates, the excellent preservation and high sedimentation rates will allow detailed isotopic studies to determine surface- and bottom-water temperatures through time. There is a unique opportunity to build Southern Ocean correlations between various microfossil groups—calcareous nannofossils, planktonic foraminifers, diatoms and radiolarians, and dinocysts, spores, and pollen. Geochemical studies have identified some unusual trends in the sequences, and the Paleogene sequence contains thin, almost-mature hydrocarbon source rocks at most sites.

Leg 189 results essentially encapsulate the Antarctic Cenozoic evolution from “Greenhouse” to “Icehouse.” The changes recorded in the cored sequences clearly reflect evolution of a tightly integrated, and at
times dynamically evolving, system involving the lithosphere, hydrosphere, atmosphere, cryosphere, and biosphere.

INTRODUCTION

The area between Australia’s southernmost prolongation (Tasmania and the South Tasman Rise [STR]) and Antarctica is a key to understanding global Cenozoic changes in climate and current patterns, involving

1. The breakup of Gondwana between 130 and 30 Ma (Fig. F1);  
2. The drifting of Australia northward from Antarctica;  
3. Initiation in the Paleogene to early Neogene of the Antarctic Circumpolar Current and the meridional expansion of the Southern Ocean with concomitant thermal isolation of the Antarctic continent and development of its cryosphere (Kennett, Houtz, et al., 1974, 1975); and  
4. The effects of these processes on global cooling (Fig. F2), climatic variability, and biotic evolution.

The opening of the Tasmanian Gateway between Australia and Antarctica and the only other important constriction in the establishment of the Antarctic Circumpolar Current, the Drake Passage, had enormous consequences for global climate. These consequences came in part by isolating Antarctica from warm gyral surface circulation of the Southern Hemisphere oceans and also by providing the necessary conduits that eventually led to ocean conveyor circulation between the Atlantic and Pacific Oceans. Both factors, in conjunction with positive feedbacks and other changes in the global system, have been crucial in the development of the polar cryosphere, initially in Antarctica during the Paleogene and early Neogene and later in the Northern Hemisphere during the late Neogene. Furthermore, the continued expansion of the Southern Ocean during the Cenozoic, because of the northward flight of Australia from Antarctica, has clearly led to further evolution of Earth’s environmental system and of oceanic biogeographic patterns.

The geographic position of the Tasmanian offshore region makes this a crucial location to study the effects of Eocene–Oligocene Australia–Antarctic separation on global paleoceanography. Australia and Antarctica were still locked together in the Tasmanian area until late in the Eocene, preventing the establishment of Antarctic circumpolar circulation (Fig. F1). At that time, and earlier, the water masses were separated on either side of the barrier in the southern Indian and Pacific Oceans and most likely exhibited distinct physical, chemical, and biological properties. The Tasmanian region is also well suited for the study of post-Eocene development of Southern Ocean climate, feedbacks that contribute to ice-sheet development and increased stability, and formation and variation of high-latitude climate zones. This region is one of the few ideally located in the Pacific sector of the Southern Ocean for comparison with the models of Cenozoic climate development and variation in the Indian and the South Atlantic Oceans. Therefore, an outstanding question is whether paleoceanographic variability, known from the Atlantic and Indian sectors, is characteristic of the entire Antarctic circumpolar ocean or whether there are zonal asymmetries in the Southern Ocean and, if so, when these developed.

The meridional spread of the sites on the STR (Fig. F3) is well suited for monitoring the migration of oceanic frontal zones through time,
analogous to transects on the Southeast Indian Ridge (SEIR) (Howard and Prell, 1992). The total meridional displacement of oceanic fronts on the STR is expected to be somewhat less than on the SEIR because the STR is a shallower topographical barrier to the Antarctic Circumpolar Current. The East Tasman Plateau (ETP) site is ideally located to monitor paleoceanographic changes at the interface between the East Australian Current and the Antarctic Circumpolar Current because the East Australian Current transports heat into the Southern Ocean, an important “gateway” objective.

The sites cored during Leg 189 also provide high-quality Neogene paleoclimatic and paleoceanographic records, including the Quaternary, from the southern temperate and subantarctic regions. These sequences are being employed to examine the development of surface-water productivity, oscillations in subtropical and polar fronts, changing strength of the East Australian Current, and changes related to further expansions of the Antarctic cryosphere during the middle and late Miocene.

Previous investigations have demonstrated that the Southern Ocean late Quaternary paleoceanographic record, manifested in its temperature response (Howard and Prell, 1992) and carbon cycling (Howard and Prell, 1994; Oppo et al., 1990), mirrors that of the Northern Hemisphere. This suggests similar cryospheric, atmospheric, and oceanographic variability in Southern Ocean climate during the past 500 k.y. as that of the Northern Hemisphere (Imbrie et al., 1992, 1993). However, on the Milankovitch band there appears to be a lead in the Southern Ocean, perhaps reflecting the importance of this region. For example, the potential role of Southern Ocean paleoproductivity on global climate remains a topic of significant interest. Despite the excellent documentation of latest Pleistocene Southern Ocean paleoclimate history, where variability is dominated by 100-k.y. cycles, there is a lack of fully cored sections to address the mid-Pleistocene (900 ka) transition from obliquity-dominated cycles (40-k.y. periodicity) to eccentricity-dominated (100-k.y. periodicity) cycles (Ruddiman et al., 1989) in this region. A documented Southern Ocean section over this “transitional” period was based on poor recovery (Hodell and Venz, 1992), so this important transition in global climate remains to be properly documented. However, two giant piston cores taken on the STR (Marion Dufresne, 1997) provide excellent records back to 900 ka, including this transition in orbital forcing mechanisms. The STR Ocean Drilling Program (ODP) sites will add to this record and complement subantarctic South Atlantic transect sites (Leg 177) in documenting this transition.

Major questions addressed during Leg 189 include the following:

1. How did the Antarctic Circumpolar Current develop, and what were the roles of the opening of the Tasmanian Gateway (~34 Ma) and Drake Passage (~20 Ma)?
2. When did the Tasmanian Seaway open to shallow water, and how did this affect east-west biogeographic differences, isotopic differences relating to changing climatic regimes, and geochemical differences?
3. When did the seaway open to deep waters, and how did this affect surface- and deep-water circulation?
4. How is Antarctic circumpolar circulation related to changes in Antarctic climate?
5. How did the East Antarctic cryosphere develop, and how does it compare to other sectors of Antarctica?
6. What was the nature of the Antarctic climate in the Maastrichtian to late Eocene Greenhouse period?
7. How did sedimentary facies change as the Tasmanian region moved northward, Antarctic circumpolar circulation became important, and upwelling commenced?
8. How did Antarctic surface waters develop in terms of temperature, the thermocline, and oceanic fronts?
9. How did Neogene intermediate waters evolve, and how was this evolution tied to Antarctic cryosphere development?
10. How did Australia's climate change as the continent moved northward?
11. How were changes in the marine biota tied to changes in the oceanographic system?
12. What was the tectonic history of the South Tasman Rise during the Cenozoic?

An understanding of Cenozoic climate evolution has required better knowledge of the timing, nature, and responses of the Paleogene opening of the Tasmanian Seaway (Figs. F1, F2). Early ocean drilling in the Tasmanian Seaway (Deep Sea Drilling Project [DSDP] Leg 29) provided a basic framework of paleoenvironmental changes associated with its opening but was of insufficient quality and resolution to fully test the hypothesis of potential relationships among the development of plate tectonics, circumpolar circulation, and global climate. Until now, the timing of events has remained insufficiently constrained.

The relatively shallow region off Tasmania (mostly above the present carbonate compensation depth [CCD]) is strategically well located for studies of the opening and later expansion of the Tasmanian Seaway. It is also one of the few places where almost-complete marine Eocene to Holocene carbonate-rich sequences can be drilled in present-day latitudes of 40°–50°S and paleolatitudes of up to 70°S (Fig. F4).

**Geological Setting**

**Broad Phases of Cretaceous and Cenozoic Deposition**

The Tasmanian region lay within the continent of Gondwana until breakup started during the Late Cretaceous (Fig. F5). Rifting related to the separation of Antarctica and Australia may have started as early as the Late Jurassic, and by the Early Cretaceous there was a well-developed east-west rift system along the southern margin of Australia that passed north of Tasmania through the Bass Strait (Willcox and Stagg, 1990). The rift sequences in outcrop and petroleum exploration wells are volcaniclastic fluvialite and lacustrine sediments thousands of meters thick in places. The volcanism was basic to andesitic, and the Lower Cretaceous sediments are dominantly immature lithic conglomerates, sandstones, and mudstones, with some better sorted quartz-rich sandstone bodies. They were probably derived from volcanism along what is now the east coast of Australia.

During the beginning of the Late Cretaceous, the early rifting in the Bass Strait failed and a northwest-southeast zone of strike-slip faulting, west of Tasmania, absorbed motion related to the continuing east-west rifting (Fig. F5). This motion eventually separated Australia and Antarctica (Figs. F6, F7). During the Late Cretaceous, the sea intruded into the rift from the west, along the gulf between Australia and Antarctica, here named the Australo-Antarctic Gulf (Fig. F1). Data from petroleum ex-
ploration wells show that coastal plain to shallow-marine detrital sediments were deposited along the east-west rift (Smith, 1986; Lavin, 1997; McKerrow et al., 1998) and also along the northernmost part of the zone of strike-slip faulting (Moore et al., 1992). In depocenters near Tasmania, these sediments are relatively mature, quartz-rich and 1000–2000 m thick (Moore et al., 1992). However, southwest of Tasmania, dredging has recovered immature, shallow-marine lithic sandstones and mudstones (Hinz et al., 1985; Exon et al., 1992) of Late Cretaceous age that are reminiscent of the Lower Cretaceous rocks farther north. Seismic reflection profiles show that these sequences are frequently progradational and deltaic (Hill et al., 1997b).

Australia’s Eastern Highlands were uplifted at the end of the Early Cretaceous at ~95 Ma (O’Sullivan et al., 1995), and rifting commenced between Australia to the west and the Lord Howe Rise and the Campbell Plateau to the east. During the Campanian (75 Ma, Chron 33), drifting of the latter elements to the east-northeast was well established (Royer and Rollet, 1997), and the eastern margin of Australia/Tasmania/STR began to collapse. In the upper Paleocene to lower Eocene, apatite fission dating indicates uplift and erosion along the western and eastern margins of Tasmania (O’Sullivan and Kohn, 1997).

In the latest Cretaceous to Eocene, the east-west rift continued to fill with prograding shallow-marine detrital sediments and coal-bearing strata. The depression along the strike-slip zone also filled with prograding sediments, and seismic interpretation suggests the depocenter moved southward with time relative to Tasmania, with Paleocene sedimentation dominating in the north and Eocene in the south (Hill et al., 1997b). Paleogene sediments are as thick as 1500 m in places. In the Oligocene, Australia cleared Antarctica, its margins subsided, and deposition of relatively thin hemipelagic, pelagic, and shallow-water carbonate predominated thereafter.

**Tasmanian Offshore Region**

Today, the Tasmanian offshore region consists of continental crust of the Tasmanian margin (Moore et al., 1992; Hill et al., 1997b), the STR (Hinz et al., 1985; Exon et al., 1996, 1997b), and the ETP (Exon et al., 1997a) and is bounded on all sides by oceanic abyssal plains (Fig. F3). Oceanic crust to the east was created by the seafloor spreading that formed the Tasman Sea in the Late Cretaceous and Paleogene. The crust to the south and west was formed during the Cenozoic, and perhaps the latest Cretaceous, by the seafloor spreading that led to the separation of Australia and Antarctica.

The continental shelf around Tasmania (Fig. F3) is mostly nondepositional at present. The continental slope west of Tasmania slopes fairly regularly, at ~4°, from 200 to 4000 m. The continental rise lies at 4000–4500 m, and the abyssal plain is generally 4500–5000 m deep. Sampling cruises have shown that the slope is underlain by continental basement and that Upper Cretaceous and Paleogene shallow-marine sandstone, siltstone, and mudstone are widespread in deep water west of Tasmania, overlain by Oligocene to Holocene pelagic carbonates. Seismic interpretation shows that basement is overlain by several kilometers of sediments in depocenters (Fig. F8).

The current-swept STR is a large north-northwest–trending bathymetric high that rises to <1000 m below sea level (msl) and is separated from Tasmania by the northwest-trending, >3000-m-deep South Tasman Saddle (Fig. F3). The STR is a continental block, and seismic
profiles show it is cut into basement highs and deep basins with several kilometers of sedimentary section (Fig. F8). The overlying sequences in faulted basins include known Oligocene to Holocene pelagic carbonates and Paleogene marine mudstones, and seismic evidence suggests they also contain Cretaceous sediments. The top of the rise is a gentle dome with low slopes, but slopes are generally steeper between 2000 and 4000 m. The western slope is more gentle to 3000 m, but below that there is a very steep scarp trending 350°, which drops away to 4500 m as part of the Tasman Fracture Zone.

The ETP is a nearly circular feature, 2500–3000 m deep, separated from southeast Tasmania by the East Tasman Saddle (Fig. F3). Slopes are generally low, but considerably greater on the plateau’s flanks. Atop the plateau is the Cascade Seamount guyot, which formed as the result of hot spot volcanism and has yielded Eocene and younger shallow-water sandstone and volcanics. Seismic profiles show that the plateau has as much as 3 s two-way traveltime (TWT) of sediment cover (Fig. F8), which are believed to comprise mainly Oligocene to Holocene pelagic carbonates and Cretaceous to Eocene siliciclastic sediments. These are underlain by continental basement rocks.

The structural setting of Sites 1168–1172 is shown in Figure F9. The west Tasmanian margin is cut by strike-slip faults, trending north-northwest or northwest, that were most active in the latest Cretaceous to mid-Paleocene (Hill et al., 1997b). They were generated by the north-west movement of Australia away from Antarctica. The STR is cut by these early faults, and also by younger, middle Eocene- to late Oligocene-age faults. These younger faults are largely north-south–trending strike-slip faults, and on the northwestern STR are related east-west–trending normal faults (Exon et al., 1997b). The three sets of faults all have throws reaching as much as 3 km. Sites 1168–1172 were all located in depocenters to ensure that thick Cenozoic sections with high sedimentation rates would be cored.

Plate Tectonics

Early extension between Australia and Antarctica began in a northwest-southeast direction during the Late Jurassic (Willcox and Stagg, 1990), and this motion created much of the western margin off Tasmania. Subsidence studies along the southern Australia margin, as well as the conjugate pattern of magnetic anomalies off Australia and Antarctica, suggest that the breakup between Australia and Antarctica propagated toward Tasmania from the Great Australian Bight (Mutter et al., 1985). Seafloor spreading may have started west of Tasmania during the Late Cretaceous and continued at a slow rate until the early Eocene, when fast spreading began. The northerly trajectory of the central STR since Australia-Antarctic separation, and its paleolatitudes since the Campanian, are shown in Figure F4. Royer and Rollet (1997) reexamined the seafloor magnetic anomaly data and satellite-derived gravity data in the region along with plate tectonic reconstructions and concluded the following about the region south of Tasmania (Fig. F10):

1. The STR is composed of two distinct domains of different origin: a western terrane, lying between the Tasman Fracture Zone and a N170°E oriented boundary at 146.5°E, was initially part of the continental shelf of north Victoria Land, Antarctica (and adjacent to west Tasmania); whereas an eastern terrane, east of the 146.5°E boundary, rifted from Tasmania and the ETP.
2. The western terrane rifted from Antarctica during the late Paleocene to early Eocene and was welded to the eastern terrane. Then, until the early Oligocene (Chron 13), when the STR cleared the Antarctic margin, the western domain underwent severe wrenching and left-lateral shearing between the Antarctic shelf break and the 146.5°E boundary. Deformation continued, but perhaps to a lesser extent, along the transform margin until the early Miocene.

3. The western margin of the STR became active as a transform in the late Paleocene to early Eocene; the SEIR axis was in contact with the margin rim from the early Eocene (~Chron 24) until the early Miocene (~Chron 6B, 23 Ma), after which the transform margin became passive.

4. Seafloor spreading initiated in the Tasman Sea in the Campanian (Chron 34), north of the ETP. A spreading center also probably initiated between the STR and the ETP during the Campanian (Chron 33) and failed shortly afterward during the Maastrichtian (~Chron 30).

Earlier Drilling (DSDP) Results

During DSDP Leg 29, four partially cored sites were drilled in the Tasmanian region (Kennett, Houtz, et al., 1975) (Fig. F3; Table T1). The three sites most relevant to the goals of Leg 189 are Site 282 on the west Tasmanian margin, Site 281 on the STR, and Site 280 on the abyssal plain immediately south of the STR (Fig. F3). The Leg 29 sites were generally located on regional highs to minimize the depth of penetration necessary to reach older strata, and hence much of the succession was cut out by hiatuses. Furthermore, during the first scientific drilling in the area, total sediment recovery for the three critical sites was fairly low (Table T1).

Site 282 was drilled to 310 mbsf on a basement high in deep water west of Tasmania. This sequence includes much of the Cenozoic but contains four major unconformities. The sequence consists of a veneer of Pleistocene ooze, underlain by upper Miocene ooze, lower Miocene marl, lower to mid-Oligocene mudstone, and upper Eocene mudstone. The sediments rest on presumed Tertiary pillow basalts. There is little in the sediments to suggest that the site was located in deep water until the margin began to subside during the Oligocene. Calcareous microfossils are present throughout, and total core recovery was 20%.

Site 281 was drilled to 169 mbsf on a basement high of quartz-mica schist of latest Carboniferous age southwest of the crest of the STR. The sequence consists of Pliocene–Pleistocene foraminifer-nannofossil ooze, Miocene foraminifer-nannofossil ooze, upper Oligocene glauconite-rich detrital sand, and upper Eocene basement conglomerate and glauconitic sandy mudstone. Evidence from the recovered intervals suggests that the site subsided into deep water after the Miocene. Calcareous microfossils are present throughout, and total core recovery was relatively high (62%).

Site 280 was drilled to 524 mbsf, on a basement high in deep water southwest of the STR (Fig. F3), and bottomed in an “intrusive basalt,” almost certainly associated with oceanic crust. The site penetrated a veneer of upper Miocene to upper Pleistocene clay and ooze, underlain (beneath a sampling gap) by 55 m of siliceous lower Oligocene sandy silt, and 428 m of middle Eocene to lower Oligocene sandy silt, containing chert in the upper 100 m and glauconite and manganese micronod-
ules in the lower succession. The lower 200 m is rich in organic carbon (0.6–2.2 wt%). The younger part of the lower Oligocene to upper Eocene sequence contains abundant diatoms, but the lower part is almost completely devoid of pelagic microfossils. All sediments were assumed to have been deposited in abyssal depths. A brown organic staining suggests that reducing conditions were present in parts of the upper Oligocene and lower Miocene. Total core recovery was only 19%.

Site 281, in particular, assisted with the development of a broad, globally significant history of Cenozoic paleoceanographic events. Shackleton and Kennett (1975) produced composite foraminiferal oxygen and carbon isotopic curves for the late Paleocene to the Pleistocene from Sites 277, 279, and 281. This record, although of relatively low resolution, exhibits the now classically known general increase in oxygen isotopic values, reflecting a decrease in bottom- and surface-water temperatures and/or ice buildup during the Cenozoic. A general increase occurred in isotopic values following the early Eocene, with a rapid increase during the early Oligocene reflecting major cryosphere expansion and cooling. Average oxygen isotopic values remained steady but oscillatory until the middle Miocene, when another rapid oxygen isotopic increase records further expansion of the Antarctic cryosphere. This was followed by additional increases in oxygen isotopic values reflecting the development of the West Antarctic Ice Sheet during the late Miocene and the Northern Hemisphere cryosphere during the late Pliocene (Fig. F2). Isotopic analyses were made at Site 281 (STR) on the lower Miocene to the Pliocene and at Site 277 (Campbell Plateau) on upper Paleocene to lowermost Miocene.

**Modern Hydrography**

The two northernmost sites drilled during Leg 189 are located in temperate (cool subtropical) waters north of the present-day position of the Subtropical Front or Subtropical Convergence (Fig. F11). The sedimentary sequences drilled during Leg 189 should record migrations of these fronts as a result of climatic change. Furthermore, as a result of plate tectonic motion, the Tasmanian continental block migrated northward in relation to these fronts during the Cenozoic, leaving records in the marine sediments. The southern sites drilled during Leg 189 are located in subantarctic waters between the Subtropical Front and the Subantarctic Front. The area drilled during Leg 189 therefore lies north of and straddling the Subtropical Front and south to the region near the Subantarctic Front. The Polar Front lies farther to the south of our southernmost site. Rintoul and Bullister (1999) showed that the Subtropical Front is centered on 46°S and lies just south of the saddle between Tasmania and the STR. The Subantarctic Front is centered on 51°S and lies ~200 km south of the STR. The Polar Front is centered on 53°S, ~200 km south of the Subantarctic Front. The Subtropical Front is marked by a zone of rapid north-south decrease in temperature and salinity and an increase in dissolved nutrients (Barrows et al., 2000) and is approximated by the 34.8–35.1 isohalines and the −10°C winter and the −15°C summer isotherms in the southern Tasman Sea (Garner, 1959). During summer, sea surface temperatures are >15°C north of the Subtropical Front, ~10°C between the Subtropical Front and the Subantarctic Front, ~8°C between the Subantarctic Front and the Polar Front, and <6°C south of the Polar Front. During midwinter, sea surface temperatures are several degrees lower.
Subantarctic surface water south of the Subtropical Front is driven
eastward across the STR by the prevailing westerly winds as the northern
part of the Antarctic Circumpolar Current. These surface currents
extend to great depths, sweeping the seabed as deep as 2000 m in places. The East Australian Current is a western boundary current that
flows southward along the east coast of Tasmania to the vicinity of the
ETP. Here, subtropical surface water converges with cooler, less saline
subantarctic surface water at the Subtropical Front (Orsi et al., 1995).

**SCIENTIFIC OBJECTIVES**

**Paleogene History**

Previous sampling has shown that basinal Paleocene history was
probably similar in two areas, the west Tasmanian margin and the STR.
Clearly, there were differences in Eocene shallow-marine deltaic deposition
between the areas, when the northern area experienced more carbonaceous sedimentation while the southern area experienced deposition
of siliceous radiolarian-bearing glauconitic mudstones. Overall, results are summarized by Hill et al. (1997b), Exon et al. (1997a), and
Exon et al. (1997b). As Australia cleared Antarctica, submarine erosion
in both areas formed an Oligocene unconformity, and both areas subsided steadily. However, the southern area sank vertically as a block,
whereas the west Tasmanian margin rotated downward from a hinge-line near the coast, increasing water depths with increasing distance
from Tasmania. In many southern areas, the Antarctic Circumpolar Current removed most Neogene sediments, but thick late Oligocene to
Holocene carbonate sediments are present in depocenters off west Tasmanian and on the STR.

The stratigraphy of petroleum exploration wells on the west Tasmanian continental shelf was summarized by Moore et al. (1992). The detrital Upper Cretaceous sequence is probably disconformably overlain
by Cenozoic strata. Nonmarine to shallow-marine, Paleocene to lower Eocene fining-upward sequences are always present. The middle Eocene
to lower Oligocene sequence is more calcareous, consisting of shallow-marine sandstone, marl, and limestone. Above a major unconformity,
the late Oligocene and younger sediments are dominantly shelfal marl
and limestone. All of the Upper Cretaceous, Paleocene, and Eocene siliciclastic sediments sampled are interpreted as shallow or restricted marine and are commonly deltaic (prograding is marked in the seismic profiles).

Existing stratigraphic and sedimentologic information indicates that middle Eocene sequences are different in the northern sites west of Tasmania (DSDP Site 282; Hill et al., 1997b) and in the south in the STR (DSDP Site 281; Exon et al., 1997b), although shallow-marine and deltaic facies are found in both areas. Northern sequences contain abundant organic matter and calcareous temperate microfossil assemblages. Southern sequences contain more siliceous microfossils of colder water character. One occurrence of varves (Exon et al., 1997b) suggests strong seasonality of the Antarctic climate. The middle Eocene to upper Oligocene sequences are crucial to understanding the opening of the Tasmanian Gateway between Tasmania and Antarctica, initially in shallow and later in deep water. Before the Oligocene, sequences on either side of the STR should have distinctive biogeographic characters.
Study of the uppermost Eocene through Oligocene sequences will be of special importance in examining the timing of the development of the circumpolar circulation both across and south of the STR (~65°S at that time). The opening of the Tasmanian Gateway was such a profound event that biotic, sedimentologic, and geochemical parameters would almost certainly have undergone distinct changes. When studied in detail and in unison, changes in these parameters are expected to provide the crucially needed evolutionary information on the gateway. The dating of unconformities or hiatuses will provide critical information on major current activity during the Oligocene, especially in the shallow sequences, although sites have been selected to minimize the effects of sediment erosion. We are especially interested in the timing of initial shallow-water linkage across the STR and deep-water linkage south of the STR.

Sites 1168 and 1170 will provide data about the Indian Ocean paleoenvironment before the opening of the Tasmanian Gateway (middle to late Eocene), whereas Sites 1171 and 1172 will provide information about South Pacific paleoenvironments before the opening. All sites will address the initial shallow-water breakthrough (late Eocene), and most will address the deep-water breakthrough to some extent (early–mid-Oligocene?).

Results from DSDP Leg 29 suggested that a sequential appearance of marine microfossils, from dinocysts and arenaceous foraminifers (early Eocene) to calcareous nanofossils (middle Eocene) to calcareous benthic foraminifers (early late Eocene) and to planktonic foraminifers (late late Eocene), might well be revealed at most of the sites. The order of appearance of major groups is paleoenvironmentally significant and is expected to provide crucial insights about the evolution of the Southern Ocean biota. The upper middle Eocene to the lower Oligocene sequence, where calcareous microfossils are present and sedimentation rates were expected to be 1.5 to 3 cm/k.y., should provide excellent documentation of tectonic, climatic, and oceanographic changes. Planktonic foraminiferal and calcareous nanofossil biostratigraphy, in conjunction with strontium and oxygen isotopic stratigraphies should provide a chronology of sufficient resolution. Specific stratigraphic boundary events (e.g., Eocene/Oligocene and Miocene/Pliocene) will be analyzed at high resolution.

**Neogene and Quaternary History**

Data from the coring in the Tasmanian region will assist in evaluation of the dynamic oceanographic and climate evolution that continued in the Southern Ocean during the Neogene and Quaternary. Information gained will include that related to climate and ocean evolution, ocean temperature oscillations, ocean front migrations, paleo-productivity, and biotic evolution. This leg is complementary to three recent ODP Neogene paleoceanographic legs: Leg 182 in the Great Australian Bight to the northwest, Leg 177 in the subantarctic South Atlantic, and Leg 181 east of New Zealand. Leg 189 fills a key geographic gap. For example, the sites provide temperate and subantarctic Neogene biostratigraphy of foraminifers and calcareous nanofossils.

In particular, the history of water-mass formation and mixing among Antarctic, Indian, and Pacific sources can be monitored in this area through isotopic and trace metal proxies measured in the abundant planktonic and benthic foraminifers. These sites will complement the Leg 177 South Atlantic subantarctic transect sites in answering ques-
tions about the Antarctic circumpolar symmetry of Southern Ocean paleoclimate change and interbasin circulation patterns that influence the ocean's dissolved carbon and alkalinity budgets.

Most recent knowledge of Southern Ocean paleoceanography has been derived from the Atlantic and Indian sectors (Legs 113, 114, 119, 120, and 177). It is usually assumed that the history from an individual site or region represents the “zonal” behavior of the Southern Ocean, but differences among the sectors may have been significant, especially for the Paleogene and early Neogene. Even in the late Pleistocene, when there is no doubt that Antarctic circumpolar flow was fully established, there is some evidence that the Atlantic and Indian Ocean sectors may have had important differences in paleoceanographic variability (Wright et al., 1991; Miller et al., 1991). These differences not only provide useful insights about paleocirculation, but also about meridional heat transport (driving zonal thermal anomalies), in the Pliocene–Pleistocene as well as in the Miocene and Oligocene (Hodell and Venz, 1992).

Intersector differences in heat transport could have important implications for the possible melting history of different segments of the Antarctic ice sheets. For example, if meridional heat transport was greater in the southwest Pacific, the West Antarctic Ice Sheet may have been more vulnerable to melting. Did this ice sheet maintain its present mass balance in the face of such circulation changes? Much work related to the cooling of Earth during the late Neogene ice ages is now focused on the role of oceanic and atmospheric polar heat transport.

Sites cored during Leg 189 will also provide records of the interaction of the Antarctic Circumpolar Current and the Western Boundary Current (East Australian Current). Areas of Western Boundary Current “injection” into the Southern Ocean (the Brazil-Malvinas Confluence and the Agulhas Retroflection) are regions of large-scale heat and carbon dioxide exchange between ocean current systems, and between the ocean and atmosphere that ventilate the main ocean thermocline, and will be one of the key components of the ocean to respond to global warming. Understanding the dynamics of such confluences on a geologic time scale is vital to anticipating their possible response to future climate change (e.g., Trenberth and Solomon, 1994).

The Neogene sites also continue global biostratigraphic transects in middle to upper bathyal water depths toward the south. West of the STR, the results from the mid-latitude Great Australian Bight Cenozoic carbonates drilled during Leg 182 (Feary, Hine, Malone, et al., 2000) will be extended southward by four of our holes to a present latitude of ~50°S. East of the STR, the results of the Lord Howe Rise Leg 90 (Kennett and von der Borch, 1986) will be extended south to the same latitude by two of our holes. An additional advantage of the northern Sites 1168 and 1172 is that these sites may contain pollen from nearby Tasmania, allowing direct terrestrial-marine climate comparisons for the Neogene. So far the only mid-latitude Southern Hemisphere drill site that has yielded such a record is Site 594 east of New Zealand (Heusser and van de Geer, 1994).
Site 1168

Site 1168 is located in middle bathyal water depths (2463 m) on the 4° slope of the western margin of Tasmania (70 km from coast) in a 25-km-wide strike-slip basin between upthrown northwest-trending ridges of Cretaceous rocks. The western Tasmania onshore margin was uplifted during the late Paleocene and early Eocene (O’Sullivan and Kohn, 1997), and this uplift and the strike-slip motion were probably coeval. The site is 80 km southeast of DSDP Site 282, which is located in deeper water and on a structural high. It lies north of the oceanographic Subtropical Front. Site 1168 was planned to penetrate marine rift to open-margin sediments deposited from the Eocene onward as Australia moved northward from Antarctica. Initially, the site was at the far eastern end of the restricted Australo-Antarctic Gulf and separated from the Pacific Ocean by the Tasmanian land bridge. Plate movements and related margin subsidence led to its Neogene location in open water facing a broad Southern Ocean. The primary objectives were to core and log (1) a prograding detrital sequence, formed during Eocene opening of the ocean south of Australia, for its paleoceanographic, paleoclimatic, and biotic history; (2) an Oligocene to present-day pelagic carbonate sequence for better understanding of the evolution of the Southern Ocean during its expansion in the Cenozoic and for high-resolution paleoclimatic studies; and (3) a Cenozoic sequence for high-resolution biostratigraphic studies.

Seismic profiles suggest that the site was subject to downslope sediment movement to the northwest in the Paleogene but was protected from downslope movement from the east in much of the Neogene by the upslope high (Fig. F12). The Paleocene and Eocene sediments prograde to the northwest, and the drilled late Eocene is hummocky in the southwest-northeast section, with ridges and troughs 0.5–1 km across, suggesting deltaic lobes. Younger sequences are poorly parallel bedded and almost transparent seismically.

We cored two advanced hydraulic piston corer/extended core barrel corer (APC/XCB) holes, and a third hole with just the APC, at Site 1168. Hole 1168A reached 883.5 mbsf with 98% recovery (Table T2). Hole 1168B was APC cored to 108.4 mbsf with 98.3% recovery, and Hole 1168C reached 290.5 mbsf with 85.4% recovery. Wireline logging was conducted in Hole 1168A with the triple-combination (triple-combo) tool string (877 to 101 mbsf) and the geological high-sensitivity magnetic tool (GHMT)-sonic tool string (730 to 102 mbsf). A bridge prevented running the GHMT-sonic tool string to the base of the cored interval, and we chose not to run the Formation MicroScanner (FMS) because of the poor hole conditions.

Construction of a composite section of the triple-cored portion of the sedimentary sequence (~110 mbsf) indicates that there are no stratigraphic gaps to that depth. Beyond that, there are limited gaps, but overall core recovery averaged 93%, producing an excellent record of near-continuous deposition since the early late Eocene. Biostratigraphy indicates no major time breaks. Sedimentation rates were relatively low throughout (6.9–1.5 cm/k.y.) for a margin setting close to land. The drilled sequence broadly consists of 260 m of nannofossil ooze of middle Miocene and younger age (lithostratigraphic Unit I); 400 m of clayey chalk, nannofossil siltstone, and sandstone of early Miocene and
Oligocene age (Unit II); and 220 m of shallow-marine carbonaceous mudstone and sandstone (Units III–V) of late Eocene age.

Lithostratigraphic Unit I (0–260 mbsf) was subdivided into two subunits: Subunit IA to 45 mbsf and Subunit IB to 260 mbsf. Subunit IA is light greenish gray foraminifer-bearing nannofossil ooze with minor calcareous turbidite sands, and Subunit IB is white nannofossil ooze. Carbonate content averages 90 wt%, and magnetic susceptibility and organic carbon content are both very low. Calcareous microfossils are abundant and little altered, benthic foraminifers are always present, dinoflagellate cysts are absent only in the middle Miocene, and radiolarians and diatoms are common in the upper Miocene. Microfossil ages (early middle Miocene to Pleistocene) show that average sedimentation rates were low at 1.65 cm/k.y. Deposition was in middle bathyal depths in well-oxygenated bottom waters.

Lithostratigraphic Unit II (260–660 mbsf) has three subunits: Subunit IIA to 410 mbsf, Subunit IIB to 540 mbsf, and Subunit IIC to 660 mbsf. These three olive-gray subunits become darker and more clayey and silty downward. Calcareous microfossils are abundant and little altered in the Miocene and moderately preserved in the upper Oligocene. Dinoflagellates and benthic foraminifers are pervasive, radiolarians are uncommon, and diatoms rarely present. Microfossil ages (late Oligocene to early middle Eocene) show that sedimentation rates were higher, averaging 4.3 cm/k.y. through the Miocene and late Oligocene. Deposition was bathyal with variation in the oxygenation of bottom waters. Visible bubbling in the cores and high methane content in headspace and vacutainer samples indicate production of biogenic gas in the upper part of the unit. An association with reduced pore-water chlorinity suggests the presence of gas hydrates, but well-log results are inconclusive. Nevertheless, the presence of fluid escape structures (soft-sediment deformation) in Subunit IIA suggests that hydrates may indeed have been present in the past.

Subunit IIA consists of clay-bearing nannofossil chalk to nannofossil claystone. Carbonate content averages 40 wt%, magnetic susceptibility is moderate, and the organic carbon content is low. Subunit IIB consists of nannofossil claystone and nannofossil-bearing claystone. Carbonate content averages 30 wt%, magnetic susceptibility is moderate, and the organic carbon content is low. Subunit IIC consists of silty nannofossil chalk to nannofossil siltstone. Carbonate content averages 40 wt%, magnetic susceptibility is fairly low, and organic carbon content is low.

Lithostratigraphic Unit III (660–748.6 mbsf) has two subunits: Subunit IIIA to 725 mbsf and Subunit IIIB to 748.6 mbsf. These two olive-gray units become darker downward. They contain calcareous microfossils that are abundant but only moderately preserved. Dinocysts and benthic foraminifers are persistent and radiolarians are uncommon. Microfossil ages indicate very low sedimentation rates in the early Oligocene. The environment of deposition was bathyal marine in a relatively tranquil environment. Carbonate content is variable but averages 20–30 wt%, magnetic susceptibility is moderate, and organic carbon content is low. Subunit IIIA consists of clayey nannofossil chalk to nannofossil-bearing organic clayey siltstone. Subunit IIIB consists of organic-bearing silty claystone and organic clayey siltstone.

Lithostratigraphic Units IV and V (748.6–883.5 mbsf) form an upper Eocene package of related sediments. These two units are dark gray to black. Carbonate content is low, magnetic susceptibility is moderate but variable, and the organic carbon content is as high as 5 wt%. Dinocysts are rare but spores and pollen are abundant, and the abundant dis-
persed organic matter is dominantly from land plants. Geochemical and micropaleontological evidence suggests periodic brackish conditions, with normal marine salinities at other times. Characterization of the organic matter indicates that it is largely terrigenous in origin and is immature, but with increasing maturity toward the base of the hole (i.e., approaching the oil window).

Two nannofossil datums give average sedimentation rates of 6.9 cm/k.y. Calcareous microfossils are sporadic, rarer downward, and moderately to poorly preserved. Agglutinating benthic foraminifers are sporadic. The environment of deposition was reducing, shelfal marine, and protected from currents and waves. Evidence from palynology suggests a subtropical to temperate climate, with a terrestrial plant assemblage containing abundant ferns. Calcareous nannofossils are represented by a warm-water assemblage containing warmer water elements than those previously found elsewhere at equivalent latitudes in the Southern Ocean. Plate reconstructions suggest that the Kerguelen Plateau may have been shielding the Australo-Antarctic Gulf from cold water from the west so that the only water entering the gulf came from warmer areas north of western Australia.

Lithostratigraphic Unit IV (748.6–762 mbsf) consists of dark gray glauconitic, quartzose sandstone, and clayey siltstone, with interbedded black carbonaceous silty claystone. Thin calcareous stringers contain microfossils. Both glauconite and quartz are fine to very coarse grained, and the quartz is subangular. Microfossil ages within this Eocene–Oligocene transition indicate low sedimentation rates during deposition of glauconite layers because of intensified bottom-water activity leading to winnowing. A condensed section with possible brief hiatuses is indicated.

Lithostratigraphic Unit V (762–883.5 mbsf) consists of black carbonaceous silty claystone and clayey siltstone and is finely laminated in part. Pyritic replacements of burrows and fossils are common. There are rare, thin lenses of rippled fine sand, and thin calcareous stringers contain microfossils.

In summary, the sediment sequence records paleoenvironmental changes, beginning with a shallow-water, nearshore, restricted basinal setting with poor ventilation and siliciclastic sedimentation, low oxygenation, and high organic carbon deposition. Site 1168 Eocene sediments, similar to those at DSDP Site 282 to the northwest and DSDP Site 280 just south of the STR, suggest widespread late Eocene anoxic conditions in the eastern Australo-Antarctic Gulf. Following a transitional phase during the Oligocene, by the Neogene these conditions had been replaced by deposition of carbonate ooze in a well-oxygenated, open ocean on a passive margin at middle bathyal depths.

The succession of sediment, climatic, and biotic changes recorded at Site 1168 reflects the three major steps in Cenozoic climate state determined by earlier researchers: “Greenhouse” in the late Eocene; “Doubthouse” of intermediate mode in the Oligocene through early Miocene; and “Icehouse” since the middle Miocene. Relatively rapid changes mark the boundaries at the Eocene–Oligocene transition and during the middle Miocene at ~14 Ma. The most conspicuous change in the sediment and biotic sequence occurred during the transition from the Eocene to the early Oligocene, with conspicuous reduction in sedimentation rates and deposition of glauconite sands. This transition reflects a transient event associated with temporarily increased bottom-water activity in the basin. The timing of this episode is consistent with the hypothesis linking the initial opening of the Tasmanian Gateway, ma-
Major cooling of Antarctica and associated cryospheric development. The changes are documented in part by excellent microfossil sequences of calcareous nannofossils, planktonic and benthic foraminifers, and dinocysts after the late Eocene. Spores and pollen are abundant in the upper Eocene, fewer in the lower Oligocene, and intermittently present in younger sequences. Major biostratigraphic achievements will be the first comprehensive Cenozoic zonations for the cool temperate region south of Australia for planktonic foraminifers, calcareous nannofossils, and dinoflagellates.

Site 1169

Site 1169 is located in deep water (3568 m) in a flat plain on the western part of the STR, 400 km south of Tasmania. It lies 30 km east of the ridge of the Tasman Fracture Zone (TFZ) that rises 400 m above the plain. The site is ~100 km south of the Subtropical Front (Subtropical Convergence). At Site 1169 we planned to penetrate open-ocean carbonate oozes deposited from the Miocene onward as Australia moved northward from Antarctica. In the early Miocene (20 Ma), the site was at 55°S compared to its present latitude of 47°S. The primary objective was to core a complete upper Neogene sequence with high sedimentation rates in northern subantarctic waters for high-resolution biostratigraphic and paleoclimate investigations.

Seismic profiles indicate that the site is in a westerly thickening wedge of transparent young Neogene ooze, ~200 m thick at the site, that apparently onlaps a prominent reflector and unconformity below, which is more transparent ooze or chalk. This wedge of ooze appears to have been deposited in the lee of the western ridge (TFZ), which provided protection from scouring by the easterly flowing Antarctic Circumpolar Current. The results from Site 1170, where a comparable section was drilled in shallower water to the east, show that the transparent wedge results from facies change rather than younging westward.

We had planned to core three APC/XCB holes, but poor weather conditions and large heaves greatly degraded the quality of the cores, and only Hole 1169A was cored to 246.3 mbsf with 91.4% recovery (Table T2). Although recovery was high in the APC cores, flow-in and other disturbances meant that both core structure and age reliability were severely compromised. This will preclude future high-resolution paleoclimatic investigations.

The drilled sequence consists of 246.3 m of nannofossil ooze with a total age range from the late Miocene (12.2 Ma) to the late Quaternary, although two disconformities removed much of the record. The upper ~200 mbsf of the sequence represents the last ~4 m.y. and disconformably overlies a thin (~200 to 220 mbsf) sequence of late Miocene age (6.5 to 6.8 Ma). This, in turn, is underlain by sediments of middle Miocene age (~12.5 Ma), although strong sediment disturbance makes for difficult dating in this part of the sequence. This time break is correlated with a seismic unconformity. Sediments are dominated throughout by nannofossil ooze with rare to common foraminifers and siliceous microfossils that include diatoms and radiolarians. Siliciclastic sediment components are largely absent in this open-ocean location. One lithostratigraphic unit is recognized, which is subdivided into two subunits: Subunit IA (0–170.1 mbsf) is a nannofossil ooze with common to abundant siliceous microfossils. Subunit IIB (170.1–246.3 mbsf) is a nannofossil ooze with rare to few siliceous microfossils. Sedimenta-
tion rates were low (1.6 cm/k.y.) during the Quaternary through late Pliocene, very high (20 cm/k.y.) during the early Pliocene, and moderately high (10.9 cm/k.y.) during the brief late Miocene interval represented. The nannofossil oozes were deposited in upper abyssal water depths under well-oxygenated bottom-water conditions.

Although the primary objective, high-resolution climatic history, could not be met, Site 1169 provides a number of highlights. We were able to develop a useful, although relatively broad, integrated subantarctic biostratigraphy for the Pliocene and Quaternary involving planktonic foraminifers, calcareous nannofossils, diatoms, radiolarians, and organic dinocysts. Ostracods are also persistently present throughout. Few previous sites from the subantarctic region have allowed the development of such an integrated stratigraphy, particularly from the Australian sector of the Southern Ocean. This site also contains the southernmost late Neogene dinocyst record ever found. A conspicuous level of microtektites was discovered in association with the latest Miocene/earliest Pliocene disconformity, the first of this age to be reported from the Southern Ocean. Conspicuous late Miocene unconformities suggest intensification of bottom-water circulation during that time and associated carbonate dissolution on the STR at depths close to 3.5 km.

Planktonic microfossil assemblages reflect the influence of both subantarctic and temperate water masses in this northern subantarctic location. These mixed assemblages may indicate shifts in position of the Subtropical Convergence over the region. Antarctic elements are also present in some planktonic microfossil groups, reflecting influence of more highly productive Antarctic surface waters to the south. The very high sedimentation rates of the early Pliocene at this site have previously been observed over broad areas of the South Pacific and elsewhere (Kennett, von der Borch, et al., 1986). These high rates were considered to represent a significant increase in calcareous biogenic productivity associated with fundamental paleoceanographic changes affecting surface waters during early Pliocene warmth. Rates of early Pliocene biogenic sedimentation at Site 1169 may have been further amplified by winnowing of calcareous nannofossils from the STR into the local catchment basin in which Site 1169 is located. Site 1169 extends observations for the first time to the subantarctic region of remarkably high early Pliocene biogenic productivity.

Site 1170

Site 1170 is located in deep water (2704 m) on the flat western part of the STR, 400 km south of Tasmania and 40 km east of Site 1169. It is 10 km west of a fault scarp, ~500 m high and trending north-south, that separates the lower western and higher central blocks of the STR. The site lies within present-day northern subantarctic surface waters, ~150 km south of the Subtropical Front and well north of the Subantarctic Front. The primary objectives of Site 1170 were to core and log (1) an Eocene detrital section deposited during early rifting between the STR and Antarctica to ascertain marine paleoenvironmental conditions before and leading into the initial marine connection that developed between the southern Indian and Pacific Oceans as the Tasmanian gateway opened during the mid-Paleogene, (2) an Oligocene to Holocene pelagic carbonate sequence to document the paleoceanographic and paleoclimatic responses to the opening of the Tasmanian gateway and subsequent expansion of the Southern Ocean, and (3) an upper Neo-
gene sequence to construct a high-resolution subantarctic biostratigraphy and a high-resolution record of paleoclimatic change.

Plate tectonic reconstructions show the site as being in the broad northwest-southeast Tasmanian-Antarctic Shear Zone during the Cretaceous and moving south with Antarctica until the latest Cretaceous, when it became welded to the remainder of the STR as part of the Australian plate. From the earliest Paleogene, the site was close to the active rift. A shallow sea associated with Paleogene rifting and east-west spreading between Australia and Antarctica placed the site in the far southeastern corner of the restricted Australo-Antarctic Gulf, on the Indian Ocean side of the Tasmanian land bridge. The ridge of the TFZ, 80 km west of the site, formed soon after fast spreading began in the middle Eocene and must have provided east-flowing debris. Marine magnetic lineations show that in the late Oligocene (26–27 Ma) the east-west spreading axis was just west of the TFZ at Chron 8. The passing of the axis probably caused nearby uplift followed by subsidence.

Seismic profiles and regional correlations suggest that the site was subject to steady deposition of prograded siliciclastic deltaic sediments from the Cretaceous into the Eocene, and hemipelagic sedimentation grading to pelagic sedimentation thereafter (Fig. F13). Much of the Cenozoic siliciclastic detritus must have come from the higher central block 10 km to the east, believed to consist largely of continental basement and Cretaceous to Eocene sedimentary rocks. Parts of the central block, which was initially the Tasmanian land bridge, may have remained subaerial and, hence, a source of siliciclastic sediments well into the Oligocene. Seismic profiles suggest that there was a period of current erosion against the fault scarp of the central block, probably during the Miocene. A wedge of sediments was deposited in the depression.

At Site 1170 we cored one APC/XCB hole, two more with the APC, and a rotary-cored hole (Table T2). Because suboptimal weather conditions affected the APC coring, construction of a composite section of the triple-cored portion of the sedimentary sequence was possible only to 70 mbsf (early late Pliocene). Beyond that, there are limited gaps, but overall core recovery averaged 90.4%. Hole 1170A reached 464.3 mbsf with 81.8% recovery. Hole 1170B was APC cored to 175.8 mbsf with 102.2% recovery, and Hole 1170C reached 180.1 mbsf with 99.7% recovery. Hole 1170D was rotary cored from 425 to 779.8 mbsf with 81.1% recovery. Wireline logging was conducted over ~540–770 mbsf in Hole 1170D with the triple-combo string, the GHMT-sonic tool string, and the FMS-sonic tool. Logging was terminated when the drill pipe became stuck in the hole, and the bottom-hole assembly had to be severed with explosives.

Site 1170, with a total sediment thickness of 780 m, ranges in age from middle Eocene (43 Ma) to Quaternary. The older sequence consists broadly of ~282 m of rapidly deposited shallow-water silty claystones of middle and late Eocene age (lithostratigraphic Unit V, see below), overlain by 25 m of shallow-water glauconite-rich clayey siltstone deposited slowly during the latest Eocene to earliest Oligocene (Unit IV). Unit IV is overlain by 472 m of slowly deposited deep-water pelagic nannofossil chalk and ooze of early Oligocene through Quaternary age (Units III–I); limestone and siliceous limestone beds are low in the Oligocene section. There is a hiatus of ~4 m.y. in the mid-Oligocene between Units IV and III. The Neogene is almost completely continuous except for a hiatus of ~4 m.y. in the upper Miocene.

The lithostratigraphic sequence has been divided into five units and a number of subunits.
Lithostratigraphic Unit I (0–93 mbsf), of early Pliocene to Pleistocene age, is a nannofossil ooz with abundant siliceous microfossils. It is generally white with some darker laminations and bioturbation. Carbonate content averages 80 wt%, and organic carbon content is <1 wt%. Average sedimentation rates are low. Deposition was in an open, well-oxygenated ocean in lower bathyal water depths. The considerable kaolinite in the clay fraction may be ancient material derived by increased wind erosion from a more arid Australia.

Lithostratigraphic Unit II (93–373 mbsf) of early Miocene to early Pliocene age has three subunits: Subunit IIA to 181 mbsf, Subunit IIB to 290 mbsf, and Subunit IIC to 373 mbsf. The unit generally consists of white nannofossil ooze or chalk, with more calcium carbonate (average 95 wt%) than Unit I. Organic carbon content is generally very low (<0.5 wt%) between 220 and 270 mbsf. Average sedimentation rates are low. Deposition was in lower bathyal water depths in open-ocean conditions.

Subunit IIA is late early Pliocene to late middle Miocene in age. It is uniform white nannofossil ooze with laminations that are light bluish to greenish gray. Subunit IIB is an upper to lower middle Miocene white nannofossil ooze that lacks laminations. Subunit IIC is white nannofossil ooze to chalk, with some laminations that are light bluish to greenish gray. The presence of quartz grains in the lower middle Miocene supports the evidence from the seismic profiles of a period of increased current activity and scouring (removing all the Oligocene) against the scarp 10 km to the east.

Lithostratigraphic Unit III (373–472 mbsf) is a light greenish gray nannofossil chalk of early Miocene to earliest Oligocene age. The lower part of the unit (below 446.6 mbsf), which is more clay rich, also contains pale gray clay-bearing limestone with evidence of pressure solution and thin hard siliceous limestone layers. Calcium carbonate percentages are lower (78 to 93 wt%) than in Unit II. Both calcareous (foraminifers and nannofossils) and siliceous (diatoms and radiolarians) microfossils are abundant throughout the unit. Organic carbon content is very low, except in the lower part where it reaches ~0.5 wt%. Sedimentation rates are moderate. Paleoenvironmental indicators suggest increasing water depths and more oxygenation from outermost shelf or upper bathyal depths in the lower part of the unit to perhaps lower bathyal depths in the upper part. Although the contact between the limestone and underlying siltstone is very sharp, the sediment character in the lowermost part of the limestone suggests a continued shallow-water influence.

Lithostratigraphic Unit IV (472–497 mbsf) is a dark greenish gray, glauconitic-rich, sandy to clayey siltstone of earliest Oligocene to latest Eocene age. Crystalline quartz, diatoms, and glauconite are very abundant in the upper part of the unit, but decrease downward as it becomes more clayey. About 1.5 m below the top of the unit, there is a break between sandier and harder sediments above and muddier sediments below. Calcium carbonate content is very low (5 wt% average, but as much as 10 wt%) and calcareous fossils are rare, whereas organic carbon content increases to <1 wt%. Carbonaceous fragments and bioturbation are ubiquitous. Sedimentation rates are low. Abundant palynomorphs (dinocysts, spores, and pollen) suggest a cool climate, and temperate forest was on the adjacent land. The clay minerals (illite/smectite) tend to support the evidence of cool climate. The lithologic transition to the underlying sequence is gradational.
Lithostratigraphic Unit V (497–779.8 mbsf) is a bioturbated, dark gray, glauconite-bearing silty claystone to clayey siltstone of late to middle Eocene age that has two subdivisions: Subunit VA to 534.9 mbsf and Subunit VB to 780 mbsf (total depth). Calcium carbonate content is low (<5 wt% on average) and calcareous microfossils are rare. Organic carbon exhibits a steady downward increase from ~0.5 wt% in the upper part of Unit V to <3.5 wt% toward the base. Sedimentation rates are high. Palynomorphs and clay minerals (mainly smectite) both suggest that conditions were warm, and rainforests cloaked the nearby land. Dinocysts are present in massive concentrations.

Subunit VA is late Eocene in age. It consists of clayey quartzose siltstone with glauconite-rich intervals and some carbonate. Subunit VB is an upper middle Eocene silty claystone. Some horizons contain abundant small (1 mm diameter) white siliceous tubes. There are occasional occurrences of volcanic glass, solitary corals, bivalves, and pyrite nodules. There are also some decimeter-thick beds of grayish or brownish limestone in the lower part.

From a generalized biostratigraphic perspective, calcareous nannofossils at Site 1170 are abundant except in the lowermost Oligocene and the Eocene. Planktonic foraminifers and diatoms are abundant down to the middle Miocene but generally decline in older sediments. Benthic foraminifers are present, except in the upper Eocene, and suggest that water depths were 50–100 m during the middle and late Eocene and deepened rapidly during the early Oligocene. Dinoflagellate cysts are common down to the upper Pliocene, are abundant in the lowermost Oligocene and upper Eocene strata, and reach massive concentrations in the Eocene. In the middle Eocene, dinoflagellate cysts, diatoms, and nannoplankton show intriguing cycles thought to be related to variations in nutrient levels (degree of eutrophication), perhaps related to fluctuations in sea level and/or ventilation. Calcareous nannofossils suggest the possibility of two long hiatuses, one in Unit IV (Eocene/Oligocene boundary) and the other in Subunit VB (middle/late Eocene boundary). However, the existence of such hiatuses is refuted by sedimentologic, and paleontologic (palynomorphs + diatoms) information.

Sedimentation rates determined from the fossil record were rapid (10 cm/k.y.) during the early rifting phase of the middle Eocene, followed by slow sedimentation and condensed sequences during the late Eocene, slow sedimentation during the early Oligocene (1 cm/k.y.), moderate sedimentation for a brief period during the late early Oligocene (5 cm/k.y.), slow sedimentation from the mid-Oligocene to the early middle Miocene (1 cm/k.y.), rapid sedimentation during the late middle Miocene (4 cm/k.y.), and slow sedimentation to the present day (2 cm/k.y.). Intervals of minimal sedimentation or erosion mark the late Oligocene and late Miocene sequences.

The geochemistry data show a very sharp change at the base of the carbonates at the Eocene/Oligocene boundary. This sharp change is associated with a diffusion barrier for pore waters and dissolved gases (e.g., methane is abundant below the barrier but absent above). Organic carbon below the barrier averages 0.5 wt% and is dominantly marine in origin. However organic carbon peaks up to 2 wt% in the lower part of the Eocene and appears to have been caused by increased nonmarine input. A variety of evidence suggests that, despite an only slightly higher than normal present-day thermal gradient, the organic matter is nearing thermal maturity. Gases deep in the hole may have been produced thermogenically, and bitumen traces appear to be present. As at
Site 1168, pore waters become fresher with depth. Determination of the source of the fresher (low Cl\(^{-}\)) waters awaits further work.

The wireline logs covered only Subunit VB in the bottom of Hole 1170D because of hole stability problems. However, they show a very clear cyclicity of 4.1 m in the Th log, which awaits more paleontologic control before it can be converted into a time series. Magnetostratigraphy provided better results than at Site 1168, but these were convincing only in the Pliocene–Pleistocene, the middle and upper lower Miocene, and the uppermost Oligocene intervals.

The sedimentary succession of Site 1170 records three major phases of paleoenvironmental development:

1. Middle to early late Eocene rapid deposition of shallow-water siliciclastic sediments during rifting between Antarctica and the STR, a time of minimal or no connection between the southern Indian and Pacific Oceans.

2. A transitional interval of slow sedimentation, with shallow-water upper Eocene glauconitic siliciclastic sediments giving way suddenly to lowermost Oligocene clayey biogenic carbonates, representing the activation of bottom currents as the Tasmanian Gateway opened and deepened during early drifting.

3. Oligocene through Quaternary deposition of biogenic carbonate sediments in increasingly deep waters and in increasingly open ocean conditions, as the Southern Ocean developed and expanded with the northward flight of the STR and the Australian continent. The sedimentary sequence, in conjunction with information from earlier ODP results, seems to record an integrated history of interplay between decreasing continental influence, rifting and subsidence of the rise, Antarctic cooling, Antarctic Circumpolar Current development, and other related factors.

A question that is being addressed by this and the other nearby sites is why there was such a sharp change from siliciclastic to carbonate sedimentation at the Eocene/Oligocene boundary. A very broad, shallow Australian-Antarctic shelf had been supplied with siliciclastic sediment for tens of millions of years, and, even though rifting, subsidence, and compaction had begun early in the Cretaceous, sedimentation kept up, and shallow marine sediments were deposited. In the Tasmanian-STR area, there was also subsidence related to the Late Cretaceous opening of the Tasman Sea. Rifting between Australia and Antarctica gave way to almost complete separation of the continents and fast spreading during the middle Eocene (43 Ma). This separation could be expected to increase the rate of subsidence, after a time lag, as the thermal anomaly under the margin dissipated. At Site 1170, siliciclastic sedimentation kept up until the Eocene/Oligocene boundary (33 Ma), some 10 m.y. after the onset of fast spreading, even though the local sedimentation rate had declined in the late Eocene. A variety of information suggests that the ridge of the TFZ formed during the middle Eocene fast spreading and was probably a major source of clayey detritus until the late Eocene. Then, the climate changed quickly, the supply of siliciclastics dropped off, slow deposition of pelagic carbonate was established, and the sea deepened rapidly. The most likely explanation is that climatic cooling led to greatly reduced rainfall, weathering, and erosion, and hence to greatly reduced siliciclastic supply. Such changes, from siliciclastic to biogenic sedimentation, appear to be apparent and synchronous wherever ODP drilling has taken place on the Antarctic margin.
In summary, the Eocene siliciclastic sedimentary interval contains a remarkable sequence of abundant organic dinocysts, pollen, and spores in addition to sufficiently persistent calcareous microfossils to assist with age control. The microfossils will provide an integrated record of terrestrial and shallow-marine paleoclimatic history of the Antarctic continental margin in the middle Eocene through early Oligocene. The Oligocene pelagic biogenic sediments provide a sequence of calcareous and siliceous microfossils for integrated studies of the early development of the Southern Ocean, as the STR both subsided and migrated toward the north. The younger Neogene succession generally contains a sequence of calcareous and siliceous microfossils that are abundant and well preserved throughout and will provide excellent paleoceanographic records.

Site 1171

Site 1171 is located in lower bathyal water depths of ~2150 m on a gentle southwesterly slope on the southernmost STR, ~550 km south of Tasmania and 270 km southeast of Site 1170. At 48°30'S, Site 1171 lies in subantarctic waters between the Subtropical Convergence and the Subantarctic Front. In this area, very strong surface and bottom currents are associated with the Antarctic Circumpolar Current. The major objectives were (1) to core and log an Oligocene to Holocene pelagic carbonate section to evaluate expected major paleoceanographic and paleoclimatic effects resulting from the opening of the Tasmanian Gateway near the time of the Eocene/Oligocene boundary and later development of deep Antarctic Circumpolar Current flow, (2) to core and log an expected underlying detrital sedimentary Eocene sequence to evaluate paleoenvironmental conditions during rifting of the STR from Antarctica, and (3) to obtain high-resolution sedimentary records from critical subantarctic latitudes to better understand the role of the Southern Ocean in climate changes during the Neogene.

Site 1171 is located on thinned continental crust, just west of the strike-slip boundary between the central and eastern STR blocks that moved with Antarctica until 66 Ma. The boundary is the Balleny Fracture Zone, which extends southward to Antarctica. Seismic and other data indicate that during the Late Cretaceous to Paleocene, the blocks themselves were cut by strike-slip faults that developed as Australia moved northwestward, and later northward, past Antarctica. Basins that formed in association with this tectonism are filled with ~1000 to 2000 m of Cretaceous through Eocene rift sediments deposited during steady subsidence.

Site 1171 is in a small north-south oriented rift basin, bounded to the east by the Balleny Fracture Zone. The middle Eocene fast seafloor spreading and opening to the south strengthened the basin's connection to the Pacific Ocean and its difference in setting to that of Site 1170 in the Australo-Antarctic Gulf. Seismic profiles and regional correlations suggest that the site was subject to steady deposition of prograded siliciclastic deltaic sediments through the Cretaceous into the Eocene and hemipelagic sedimentation grading to pelagic sedimentation thereafter (Fig. F14). Much of the siliciclastic detritus must have come from the high, subaerial bounding blocks of continental crust and also along the basin from the higher northern areas. The southwestern tip of the STR cleared Antarctica during the early Oligocene and deep Antarctic circumpolar circulation became established. Site 1171 was selected because of its extreme southern location on the STR, in suf-
iciently shallow water to provide a carbonate sequence unaffected by
dissolution. Thus, the site was designed to provide critical data about
STR subsidence and on the timing of the initial surface water, and later
deep-water flow, through the opening of the Tasmanian Gateway be-
tween Australia and Antarctica.

At Site 1171 we cored two APC holes, one APC/XCB hole, and a ro-
tary cored hole (Table T2). Because weather conditions were good dur-
during the APC drilling, construction of a composite section of the total
triple-cored portion of the sedimentary sequence was possible to 118
mbsf (upper Miocene). Beyond that, there are limited gaps, but core re-
covery averaged 81.8%. Hole 1171A was APC cored to 124 mbsf with
94.5% recovery, Hole 1171B was APC cored to 109 mbsf with 98.1% re-
covery, and Hole 1171C was APC/XCB cored to 275 mbsf with 89.4%
recovery. Hole 1171D was rotary cored from 248 to 959 mbsf with
73.9% recovery. The interbedded hard and soft beds from 265 to 440
mbsf greatly reduced recovery of both XCB and RCB and stopped XCB
coring earlier than desired. Because of operational problems, wireline
logging was conducted only with the triple-combo string over most of
Hole 1171D.

Site 1171, with a total sediment thickness of 959 m, ranges in age
from late Paleocene (58 Ma) to Quaternary. The Neogene section is
largely complete except for a hiatus in the uppermost Miocene. The Pa-
leogene record from the early middle Eocene to the latest Oligocene is
cut by five hiatuses, and the Oligocene is poorly represented. The older
sequence consists broadly of ~616 m of rapidly deposited, shallow-
water silty claystone of late Paleocene to late Eocene age (lithostrati-
graphic Units V and VI) overlain by 67 m of diatom-bearing claystone
of late Eocene age (lithostratigraphic Unit IV) and 6 m of shallow water,
glauconitic siltstone, deposited slowly during the latest Eocene (Unit
III). Unit III is overlain by 67 m of slowly deposited, deep-water nanno-
foossil chalk and ooze of early Oligocene to early Miocene age (Unit II);
limestone and siliceous limestone beds are in the base of the Oligocene
section. Unit I consists of 234 m of deep-water foraminifer-bearing nann-
ofossil ooze and chalk of early Miocene to Holocene age.

The lithostratigraphic sequence has been divided into six units and a
number of subunits.

Lithostratigraphic Unit I (0–253 mbsf), of early Miocene to Pleis-
tocene age, has been divided into two subunits: Subunit IA to 41 mbsf
and Subunit IB to 253 mbsf. Subunit IA is a white to light gray foramin-
iferal nannofossil ooze and foraminifer-bearing nannofossil ooze,
whereas Subunit IB is a nannofossil ooze and chalk, which is distin-
guished from Unit IA by decreasing foraminiferal content. Carbonate
content averages 93 wt% and organic carbon is very low (<0.2 wt%) in
Unit I. Average sedimentation rates were low.

Lithostratigraphic Unit II (253–270 mbsf), of late Oligocene age, is a
white to light greenish gray nannofossil chalk characterized by a
downsection increase in the detrital components (e.g., glauconite,
quartz, and mica) and a decrease in the biogenic fraction. Organic car-
bon content is low, and carbonate content decreases from 95 wt% at
the top to 75 wt% at the base. Sedimentation rates were very low.

Lithostratigraphic Unit III (270–276 mbsf) is ~6 m of dark greenish
gray to blackish green glauconitic sandy to clayey glauconitic siltstone
of late Eocene age. Carbonate content decreases from 77 wt% at the top
of the unit to 0.4 wt% at the base. Organic carbon content is extremely
low and approaches zero.
Lithostratigraphic Unit IV (276–343.5 mbsf) is a middle to upper Eocene nannofossil-bearing, diatomaceous silty claystone that darkens downsection from olive gray to dark gray and bottoms in a black chert. Carbonate content is low (5 wt%) and organic carbon averages 0.4 wt%.

Lithostratigraphic Unit V (343.5–692.5 mbsf) is composed of claystones and silty claystones of middle Eocene age and is divided into three subunits. Subunit VA consists of dark greenish gray or dark olive-gray claystone and nannofossil-bearing claystone. Carbonate content averages 14 wt%, and organic carbon content is 0.5 wt%. Subunit VB is a dark gray claystone, occasionally organic matter–bearing, and is distinguished from Subunit VA by a lower nannofossil abundance, darker color, and higher organic carbon content (average = 1 wt%). Carbonate content is very low (1 wt%). Subunit VC is olive gray to dark olive-gray silty claystone with higher nannofossil abundance and lower organic carbon (0.5 wt%) than the overlying subunit. Carbonate content averages 8 wt%. Sedimentation rates fluctuated between 4–12 cm/k.y.

Lithostratigraphic Unit VI (692.4–958.8 mbsf) is early Eocene to late Paleocene in age and has been divided into two subunits. Subunit VIA is lower Eocene greenish gray nannofossil-bearing silty claystone in the upper part and silty claystone in the lower part. Carbonate nodules and pressure solution seams are sporadic through the subunit. Carbonate content is low, averaging 2 wt%, and organic carbon is 0.5 wt%. Subunit VIB is lowermost Eocene to upper Paleocene silty claystones that give way to dark grayish brown, organic matter–bearing clayey siltstones in the lower part. The bottom ~40 m of the subunit is pervasively laminated. Carbonate content is <1 wt% and organic carbon content (0.9 wt%) is higher than in Subunit VIA. Sedimentation rates averaged 4 cm/k.y.

In general, calcareous nannofossils at Site 1171 are abundant in the Neogene and Oligocene, highly variable in abundance in the Eocene (where they are also absent in many intervals), and rare in the Paleocene. The Neogene and Oligocene are marked by highly abundant and well-preserved calcareous nannofossils and planktonic foraminifers and relatively abundant radiolarians and diatoms. In contrast, the Eocene has many intervals barren of calcareous microfossils, especially planktonic foraminifers. Radiolarians and diatoms are rare to absent throughout much of the Eocene, although neritic planktonic and benthic diatoms are common in the upper Eocene. The shallow-water Eocene siliciclastics are distinguished by a continuous record of abundant organic dinoflagellate cysts and pervasive pollen and spores, which are critical for biostratigraphic subdivision of this interval and provide a rich paleoenvironmental record. The Paleocene sediments also contain abundant assemblages of organic palynomorphs, but only rare to few calcareous nannofossils. Planktonic foraminifers, radiolarians, and diatoms are absent. Benthic foraminifers, which have provided critical information on benthic environments, are largely present throughout the entire sequence and are noticeably more abundant in the Eocene.

Sedimentation rates determined from the fossil record were rapid (4–12 cm/k.y) during the Paleocene to middle Eocene. Biostratigraphic datums indicate four brief hiatuses (~2 m.y.) interspersed with brief periods of slow sedimentation (<1 cm/k.y.) through the late Oligocene to the middle Eocene. Sedimentation rates were low, fluctuating between 0.7–2.0 cm/k.y. in the early and middle Miocene, increased to 3.8 cm/k.y across the middle/late Miocene boundary, and decreased again to a very low 0.5 cm/k.y. in the late Miocene. The Miocene/Pliocene bound-
ary is marked by a hiatus of at least 1.6 m.y., followed by slow sedimentation (1.3 cm/k.y.) in the Pliocene–Pleistocene.

A major result of the coring was the discovery that the unconformity separating flat-lying strata from gently dipping strata in seismic profiles corresponds to the Paleocene/Eocene boundary. This means that tectonism in this small basin, bounded by the major strike-slip fault system of the Balleny Fracture Zone, ended at ~55 Ma. This strongly suggests that the driving force for the strike-slip motion, the separation of Australia and Antarctica, no longer affected this part of the STR from that time, accurately defining the age of the onset of seafloor spreading to the south as 55 Ma. It is surely no coincidence that uplift of the western and eastern onshore margins of Tasmania occurred in the late Paleocene to early Eocene (O’Sullivan and Kohn, 1997).

Similar to Site 1168 on the west Tasmania margin, and Site 1170 on the eastern STR, pore-water freshening (13% decrease in Cl− relative to seawater) is also observed at Site 1171 below ~320 mbsf, which is coincident with the onset of methanogenesis but unexpectedly below the interpreted bottom-simulating reflector. Organic matter is immature through most of the cored interval, with maturity increasing with depth. However, organic matter is mature toward the base of the cored interval, and gases have a thermogenic signature, although total gas quantities are low. Characterization of the organic matter (hydrogen index) indicates three intervals of upwardly increasing marine influence in the early to middle Eocene.

The wireline logs were confined to a single complete run of the triple-combo tool in Hole 1171D because of technical and hole stability problems. Logging data display a strong cyclicity, especially the Th spectrum of the natural gamma-ray log in the middle Eocene section. Variability in log data also may record alternating marine and terrestrial influences. Distinct spikes in resistivity and density are observed in middle Eocene sediments, which likely correlate with indurated carbonates and/or glauconite and tend to be directly above Th and K peaks, indicating increased input of terrestrial clays.

The Paleogene (late Paleocene through Oligocene) depositional history is one of increasing ventilation and a major, rapid increase in water depths that began to occur near the Eocene/Oligocene boundary. This deepening causes transformation from shallow (neritic) to deep open-ocean conditions. Late Paleocene sediments were deposited in near anoxic conditions in nearshore highly sheltered environments, with resulting high organic carbon content. Early to middle Eocene neritic sediments show evidence of being less restricted as reflected by pervasive, well-developed sediment bioturbation and increasing abundance of calcareous nannofossils.

The Eocene–Oligocene transition at Site 1171 is marked by a series of distinct stepwise environmental changes, reflecting increasingly cool conditions and coeval rapid deepening of the basin. By the earliest Eocene, a change had occurred from inner neritic environments with freshwater influences and sluggish circulation, to outer neritic environments with increased ventilation and bottom-current activity. Concomitant cooling is indicated by episodic increases of endemic Antarctic dinocyst taxa, a trend that continued through the late Eocene to earliest Oligocene (~34.0–33.3 Ma). Sediments and biota indicate increasing bottom-water ventilation and more productive surface waters at slightly deeper depths (outer neritic to upper bathyal depths), with increasingly cold conditions. This trend culminated in the early Oligocene (33–30 Ma) with a distinct increase in open-ocean upwelling and rigorous ven-
tilation that precluded accumulation of organic matter, despite the overall higher surface-water productivity. At this time, slow deposition of silica-rich calcareous sediments commenced in lower bathyal depths.

As at Site 1170, the sedimentary succession of Site 1171 records three major phases of paleoenvironmental development that are consistent with the hypothesis that initial development and evolution of the middle and late Cenozoic cryosphere resulted from thermal isolation of the Antarctic by the development of the Antarctic Circumpolar Current and the Southern Ocean:

1. Late Paleocene to early late Eocene rapid deposition of shallow-water (neritic) siliciclastic sediments during rifting between Antarctica and the STR. This was a time of minimal or no connection between the Pacific Ocean, in which these sediments were deposited, and the Australo-Antarctic Gulf in the southern Indian Ocean.

2. A relatively brief transitional interval of slow sedimentation with shallow-water late Eocene glauconitic siliciclastic sediments changing suddenly to earliest Oligocene deeper water clayey biogenic carbonates. Deposition of the glauconitic sediments represents initiation of moderate current activity as the Tasmanian Gateway opened to shallow (neritic) waters. Deposition of the overlying carbonates heralds the development of open-ocean conditions in the Gateway and initiation of circumpolar circulation.

3. Oligocene through Quaternary deposition of pelagic carbonate sediments in increasingly deep waters and in increasingly open ocean conditions as the Southern Ocean developed and expanded with the northward flight of the STR and the Australian continent.

Although the history of sedimentation at Sites 1171 and 1170 exhibits the same broad regional trends, strong evidence exists that, up until the late Eocene, sediments accumulated in separate basins isolated by the Tasmanian land bridge. This is most clearly shown by the poorly ventilated depositional environment at Site 1170 vs. the relatively more ventilated environment at Site 1171. This is consistent with the interpretation of highly restricted marine conditions at the easternmost end of the Australo-Antarctic Gulf, as is also suggested by the Eocene sediment record at Site 1168 off western Tasmania.

Climatic implications resulting from interpretations of data from Site 1170 and other locations on the STR include the following:

1. The rapid transformation from Eocene siliciclastic sediments to Oligocene pelagic carbonates near the Eocene/Oligocene boundary in the STR region seems to have resulted largely from major cooling of Antarctica that caused greatly reduced rainfall, weathering, and erosion and, hence, greatly reduced siliciclastic supply. Siliciclastic sediment starvation appears to have occurred broadly at this time around the Antarctic margin.

2. No evidence for glaciation has yet been observed in the Oligocene sediments of Sites 1171 and 1170, the two southernmost sites drilled during Leg 189. This and other supporting evidence suggests that this margin of the Antarctic was warmer than other sectors.
3. A strong meridional climatic gradient appears to have existed during the Oligocene between the STR margin of Antarctica and the Ross Sea at Cape Roberts (77°S), where early Oligocene diamictites were deposited (Cape Roberts Science Team, 2000).

4. Antarctica was clearly marked by strong regional climatic differences during the Oligocene, well before a unifying Neogene circumpolar influence had developed.

5. It is unlikely that continent-wide ice sheets of proportions typical of the Neogene developed in the Oligocene.

Site 1172

Site 1172 is located in a water depth of ~2620 m on the flat western side of the ETP, ~170 km southeast of Tasmania. At 44°S, the site lies in cool subtropical waters just north of the Subtropical Front in an area where both the Subtropical Front and the East Australian Current have had variable influence through time. The primary objectives of coring and logging at Site 1172 were to obtain in the far southwest Pacific (1) an Oligocene to Holocene pelagic carbonate section under long-term influence of the East Australian Current to construct moderate- to high-resolution paleoceanographic and biostratigraphic records, (2) an Eocene siliciclastic sediment sequence for better understanding of paleoceanographic and paleoclimatic conditions before Antarctic Circumpolar Current development, (3) an Eocene–Oligocene transitional sequence to determine the effects of the initial opening of the Tasmanian Gateway on the paleoceanography of the Pacific Tasmanian margin, and (4) to compare and contrast changing paleoenvironmental and paleoceanographic conditions on each side of Tasmania as the Tasmanian Seaway opened and the Antarctic Circumpolar Current developed. This site was also expected to provide valuable information about the tectonic history of the ETP, including evolution of an inferred volcanic hot spot in the Eocene.

Site 1172 is on thinned continental crust on the western side of the ETP. The plateau is roughly circular, 200 km across, lies in water depths of 2200–2800 m, has Upper Cretaceous oceanic crust to the east and probably to the southwest and south, and is attached to Tasmania to the northwest. During the middle Eocene, the ETP was at ~65°S when its fast northward movement (55 km/m.y.) with Australia commenced. Continental basement rocks form its margins, and seismic profiles and other evidence suggest that at Site 1172 basement is overlain by gently dipping Cretaceous sediments and flat-lying Cenozoic sediments. The late Eocene Cascade Seamount is a guyot in the middle of the plateau consisting of basaltic volcanics and volcaniclastics.

At Site 1172 we cored two APC holes, one APC/XCB hole, and a rotary cored hole. Because weather conditions were good during the APC drilling, construction of a composite section of the total triple-cored portion of the sedimentary sequence was possible to 146 m composite depth (mcd) (late Miocene) (Table T2). Beyond that, there are limited gaps, but core recovery averaged 92%. Hole 1172A was APC/XCB cored to 522.6 mbsf with 92.6% recovery. Hole 1172B was APC cored to 206.7 mbsf with 102.1% recovery. Hole 1171C was APC cored to 171 mbsf with 100.9% recovery. Hole 1172D was rotary cored from 344 to 373 mbsf, drilled to 497 mbsf, and cored to 766 mbsf with 80% recovery. Despite heave of up to 10 m, wireline logging was conducted over most of Hole 1172D with successful runs of the triple-combo tool string and
the GHMT-sonic tool string. However, the heave was too great to run the FMS tool string.

The results significantly changed our precruse understanding of the history of the ETP, with much older sequences being cored at the site than expected. Site 1172 penetrated ~65 m of black shallow-marine mudstones of latest Cretaceous (Maastrichtian) age (Fig. F15). This was overlain by 335 m of Paleocene and Eocene brown, green, and gray shallow-marine mudstones and 364 m of Oligocene and Neogene pelagic carbonates. The pelagic carbonates were deposited in ever-increasing depths after rapid Oligocene subsidence, and much of the Oligocene and early Miocene sections are missing because of current action. A series of volcanic ash horizons of late Eocene to Oligocene age suggest that volcanism on Cascade Seamount continued for at least 5 m.y. The lithostratigraphic sequence has been divided into four units, with three subunits in Unit I and two subunits in Units III and IV.

Lithostratigraphic Unit I (0–355.8 mbsf), of early Miocene to Pleistocene age, is divided into three subunits: Subunit IA to 70 mbsf, Subunit IB to 271.2 mbsf, and Subunit IC to 355.8 mbsf. Subunit IA is a white foraminifer nannofossil ooze and foraminifer-bearing nannofossil ooze, whereas Subunit IB is a white and light greenish gray nannofossil ooze. The two subunits are distinguished mainly by a decrease in foraminiferal content in Subunit IB. Subunit IC is a white, pale yellow, and light gray foraminifer-bearing nannofossil chalk marked by an increase in the foraminiferal content and increasing minor components of clay and volcanic glass. Calcium carbonate content increases from 80 wt% in Subunit IA to 97 wt% in Subunit IB and decreases in Subunit IC to 90 wt%.

Lithostratigraphic Unit II (355.8–361.12 mbsf) is a thin uppermost Eocene to Oligocene transitional unit. The sediments are mainly characterized by increased glauconite and a decrease in nannofossil content and consist of variations of greenish gray glauconite-bearing silty diatomaceous claystone and dark greenish gray glauconitic diatomaceous clayey siltstone. A distinct surface at 357.27 mbsf is marked by abundant glauconite and rip-up clasts above and by angular clasts below. This transition may be a highly condensed section or a hiatus. Carbonate content decreases from 69 wt% at the top to 0.3 wt% at the base.

Lithostratigraphic Unit III (361.12–503.4 mbsf), of late to middle Eocene age, has been divided into two subunits: Subunit IIIA to 433.89 mbsf and Subunit IIIB to 503.4 mbsf. Subunit IIIA is a greenish gray and dark brownish gray diatom- and nannofossil-bearing claystone and a very dark grayish brown diatomaceous claystone. Subunit IIIB is a dark gray to dark olive-gray diatomaceous silty claystone. The two subunits are distinguished by calcium carbonate content averaging 10 wt% in Subunit IIIA and very low values, approaching zero, in Subunit IIIB.

Lithostratigraphic Unit IV (503.4–766.5 mbsf) is Late Cretaceous to early Eocene in age and is divided into two subunits: Subunit IVA to 695.99 mbsf and Subunit IVB to 766.5 mbsf. Subunit IVA is a middle Eocene to Paleocene olive-gray claystone with minor amounts of silty claystone, nannofossil-bearing claystone, and clayey siltstone. The subunit is distinguished from Unit III above by a lack of siliceous microfossils and an increase in opaque and accessory minerals, which reach a maximum of 15% at 542 mbsf. Subunit IVB is a Cretaceous (Maastrichtian) very dark olive-gray, very dark gray, and black claystone and silty claystone. It is distinguished from Subunit IVA by its darker color, lesser bioturbation, lesser glauconite content, and greater organic matter content. Sedimentological studies suggest that the Cretaceous/Tertiary (K/T)
boundary is at ~696.1 mbsf, where a distinct lithologic change occurs at the subunit boundary, from brown and highly bioturbated silty claystone above to black massive claystone below. Detailed biostratigraphic postcruise studies indicate the K/T boundary is at ~696.4 mbsf. Carbonate is generally very low with a maximum of 6.5 wt% at 762.9 mbsf.

Microfossils are present throughout the entire Cenozoic and upper Cretaceous sequence at Site 1172 with dominance of different groups drastically changing with depositional environments. Siliceous microfossils are rare to absent in the Quaternary to Pliocene interval but are common to abundant and well preserved in the Miocene. The thin Oligocene succession yielded few radiolarians, whereas diatoms remained abundant downhole. Both groups are common to locally abundant and well preserved in the Eocene. The upper Paleocene to upper Maastrichtian interval is virtually barren of siliceous microfossils, although pyritized biogenic silica is present. Planktonic foraminifers and calcareous nannofossils are generally abundant in the Neogene and Oligocene, with preservation ranging from moderate to good. Although less abundant, calcareous nannofossils remain consistently present until the middle Eocene, when abundance and preservation decrease dramatically. Below the middle Eocene, the Cenozoic succession is barren of calcareous nannofossils. Planktonic foraminifers are virtually absent below the middle/upper Eocene boundary.

Well-preserved and reasonably diversified calcareous microfossils are present in the upper Maastrichtian. Calcareous benthic foraminifers are consistently present throughout the Neogene–Oligocene carbonate succession. The middle Eocene sequence yields only rare agglutinated species. However, calcareous and agglutinated taxa are present in the Paleocene to upper Maastrichtian succession. Well-preserved organic walled dinoflagellate cysts and few sporomorphs are present in the Quaternary. The remaining Neogene to lower Oligocene strata are devoid of acid-resistant organic matter. Moderate to well-preserved dinocysts are the dominant constituent of upper Paleocene to lowermost Oligocene palynological associations and are persistent below this interval. Well-preserved terrestrial palynomorphs dominate upper Maastrichtian to middle Paleocene sediments.

Sedimentation rates at Site 1172 form three distinct phases. In contrast to other Leg 189 sites, sedimentation rates were relatively low (between 2.6 and 1.04 cm/k.y.) in the Maastrichtian through late Eocene. From the late Eocene through the middle Miocene (15 Ma) sedimentation rates decreased (0.16 to 3.2 cm/k.y) and then have increased again until the present day. These three intervals coincide with, and are probably related to, the succession in global climate change from “Greenhouse” to “Doubthouse” to “Icehouse” states. Site 1172, like Site 1168, appears to have been strategically located to sensitively record these overall shifts in global climate associated with development of the Antarctic cryosphere. The higher early Paleogene and late Neogene sedimentation rates resulted from more stable climatic conditions. These were associated with the lack of any significant early Paleogene Antarctic cryosphere in the “Greenhouse” world and a late Neogene “Icehouse” world marked by a permanent Antarctic ice sheet. Reduced sedimentation rates during the middle Cenozoic at Site 1172 were associated with more highly variable climatic conditions leading to higher rates of deep-sea erosion. The lower-than-normal regional rates of sedimentation during most of the Paleogene at Site 1172 may have resulted from pervasive, but gentle shallow-water sediment winnowing by the East Australian Current. Relatively higher rates of late Neogene
sedimentation probably resulted from higher marine productivity caused by stimulation of surface-water circulation upon middle Mio-
cene expansion of the Antarctic cryosphere.

The geothermal gradient is lower at this site than in the other Leg 189 sites. Despite TOC contents that are similar to those of other Paleo-
gene sequences at the other Leg 189 sites (0.5–1.0 wt%), complete sul-
fate reduction is not observed and only traces of methane are present. Organic matter is less mature thermally and more labile; however, there
is evidence of bitumen in the older siliciclastic sediments, which may
indicate the migration of hydrocarbons from below the drilled section. As at other sites, the presence of fresher pore waters was observed on
the ETP, which indicates the regional extent of these low chloride flu-
ids.

The sedimentary succession of Site 1172 is similar to that in the
other Leg 189 sites in recording three major phases of paleoenviron-
mental development:

1. Maastrichtian to early late Eocene deposition of shallow-water siliciclastic sediments during rifting between Antarctica and the STR, a time of minimal or no connection between the Pacific Ocean and the southern Indian Ocean.

2. A transitional interval of slow sedimentation, with shallow-
water late Eocene glauconitic siliciclastic sediments giving way
suddenly to earliest Oligocene deep-water clayey pelagic carbon-
ates representing the activation of bottom currents as the Tasman-
nian Gateway opened and deepened during early drifting.

3. Oligocene through Quaternary deposition of pelagic carbonate sediments in increasingly deep waters and more open ocean conditions as the Southern Ocean developed and expanded with the northward flight of the ETP and the Australian continent.

The sediment succession at Site 1172 generally reflects an upward in-
crease in ocean ventilation. Like the other sites drilled during Leg 189,
increased ventilation resulted from a fundamental change in paleogeog-
raphy associated with increasing dispersal of the southern continents
and the opening of the ocean basins at high latitudes in the Southern Hemisphre. Thus, the sluggish ocean circulation and restricted environ-
ments of sedimentation of the Late Cretaceous and early Paleogene were eventually replaced by well-ventilated open-ocean conditions of the lat-
er Cenozoic.

The Paleocene to middle Eocene was relatively warm based on the character of dinocyst assemblages similar to the middle Eocene record
at Site 1171. Terrestrial palynomorphs, also indicative of warm condi-
tions, are especially abundant in the lower Paleogene (Paleocene–early Eocene) sediments and suggest very shallow water restricted conditions
with marked runoff at this time. An absence of foraminifers, and even
of nannofossils, in most parts of the Paleocene to middle Eocene con-
firms the marginal marine interpretation. Maastrichtian sediments were
deposited in more open ocean conditions based on higher abundances
of calcareous microfossils, more offshore dinocyst assemblages, and few pyritized diatoms.

The middle/late Eocene boundary is marked by a change from an in-
ner neritic setting with marked freshwater influence and sluggish circu-
lation to more offshore, deeper marine environments with increased
ventilation and bottom-water current activity. Concomitant cooling is
indicated by the increased numbers of endemic Antarctic dinocyst spe-
cies, whereas warmer episodes are also recognized. The Eocene–Oligocene transition (~34.0–33.3 Ma) is marked by a series of distinct stepwise environmental changes reflecting cooling and coeval rapid deepening of the basin. Sediments and biota indicate increasing bottom-water ventilation and the appearance of highly productive surface waters, in outer neritic to bathyal depositional settings, associated with the cooling. This trend culminated in the early Oligocene (33–30 Ma) when rigorous ventilation, and generally oxygen-rich waters, precluded sedimentation of organic matter despite overall high surface-water productivity. The condensed calcareous sequence contains abundant siliceous microfossils and was deposited in an oceanic bathyal environment. Oligocene to present-day pelagic carbonates were deposited in well-ventilated open-ocean conditions.

Although Site 1172 reflects the broad patterns of Cenozoic sedimentation for the Tasmanian region, differences from other sites are almost certainly related to the site’s position astride the East Australian Current, and relatively isolated on the ETP, away from major sources of detrital sediments. A distinct increase in neritic diatoms during much of the middle Eocene appears to reflect higher productivity in this current than elsewhere on the Tasmanian margin. Increased productivity may have resulted from increased nutrient input swept into neritic environments by the East Australian Current as it moved south adjacent to Australia. A distinct upward increase in kaolinite (and illite) following the middle Miocene (~15 Ma) may reflect the increasing aridity of Australia and the transport of clays into the East Australian Current as it swept southward along the Australian margin.

A complete composite-core record was successfully obtained for the last ~8 m.y. The successful drilling of Site 1172 capped off a highly productive and satisfying coring campaign in the Southern Ocean. Much was learned at sea, and postcruise research is expected to further contribute significantly toward understanding of Southern Ocean and Antarctic environmental development and its role in Cenozoic global climate change.

**SUMMARY OF RESULTS**

**Lithostratigraphy**

We recovered a range of biogenic and siliciclastic sediments from the uppermost Cretaceous to Quaternary (Fig. F16), including the interval of the sediment sequence recording the seaway opening south of Australia and the development of Southern Ocean circulation. The sedimentary sequences allow recognition of three distinct phases of sedimentation (a siliciclastic interval, a transitional unit, and a biogenic carbonate sequence) and three sedimentary provinces (the more restricted west Tasmanian margin [Site 1168], the transitional STR [Sites 1169, 1170, and 1171], and the more ventilated ETP [Site 1172]).

The siliciclastic sequence extends from the upper Maastrichtian (drilled on the ETP) to the upper Eocene and consists of shallow-water silty claystone and clayey siltstone for the entire Tasmanian region. The siliciclastics are associated with abundant neritic diatoms from the middle Eocene in the Pacific region of the ETP. The sediment is enriched in organic matter in the poorly ventilated western Australo-Antarctic Tasmanian region. Such siliciclastics are widespread on the margins of Australia and Antarctica and have been observed from the Eocene Great...

The initiation of the transitional unit coincides with the preservation of abundant neritic diatoms in the upper Eocene on the STR, followed by the occurrence of glauconitic siltstones and sands throughout the Tasmanian region. This is indicative of greater bottom-water activity near the Eocene/Oligocene boundary. Siliciclastic sediments decrease rapidly above the glauconitic interval in the lowermost Oligocene of the ETP and the STR but persisted in the early Oligocene of the western Tasmanian margin (until ≈31 Ma.).

The STR and ETP pelagic carbonate sequence (see “Geochemistry,” p. 40) begins abruptly with the first occurrence of nannofossil chalk and limestone in the lowermost Oligocene. The STR sequence also contains common to abundant siliceous microfossils. On the west Tasmanian margin, the pelagic carbonate content increases progressively in the lower Oligocene, and the sediments consist of almost-pure nannofossil chalk by the middle Miocene. The pelagic carbonate ooze contains increased foraminifers and clay content in the whole Tasmanian region from the late Pliocene to the Pleistocene.

**Tectonics and Sedimentation**

The upper Paleocene and lower Eocene sediments on the STR decrease in grain size upsection as the clay assemblage evolves from a complex assemblage of kaolinite, illite, and smectite to predominantly smectite. This pattern reflects decreased erosion and continental relief at the end of transtensional activity that led to the development of basins from Antarctica to much of the STR. The local source region of Site 1171 was tectonically active during the late Paleocene, and that of Site 1170 during the middle Eocene (TFZ), leading to changes in clay mineral evolution at the two sites.

Beginning in the late middle Eocene, increasing grain size of the shallow-marine siliciclastics on the STR and western Tasmania margin, together with a clay assemblage dominated by illite and kaolinite, resulted from erosion of steep-continental relief. This interval correlates with a stage of late middle and late Eocene tectonism resulting from increased spreading rates in the Australo-Antarctic Gulf, and strike-slip activity on the western STR. This stage of tectonism ultimately led to the final separation of Australia from Antarctica at the Eocene/Oligocene boundary. The presence of volcanic glass on the Pacific side of the Tasmanian region and ash layers on the ETP indicate that the late Eocene interval of tectonism was associated with intensified volcanic activity that may have persisted into the early Oligocene. It remains to be determined how much of this volcanism was associated with the presumed hot spot volcano of the Cascade Seamount on the ETP and how much volcanism was related to the general tectonism.

**Environment of Sedimentation**

Extensive bioturbation of the entire upper Maastrichtian to upper Eocene sequence on the ETP and of Eocene sediments on the STR indicates significant bottom-waters ventilation. However, the absence of carbonate microfossils and the presence of siliceous microfossils suggest that major dissolution occurred and may have been associated with restricted environmental conditions. Darker sediment colors and decreased bioturbation on the western STR, together with abundant or-
ganic matter and intervals of lamination on the western Tasmanian margin, indicate poor ventilation of the Australo-Antarctic Gulf during the middle and late Eocene. Anoxic to suboxic conditions prevailed in the sheltered troughs of the Tasmanian margin. Abundant uppermost Eocene glauconite includes foraminiferal infillings indicative of in situ formation. Widespread glauconite in the entire Tasmanian region indicates strong bottom-current activity and winnowing at shelf water depths.

Bottom-water ventilation increased sharply in the earliest Oligocene, producing the light-colored sediments of the ETP and the STR, whereas ventilation developed slowly from the early Oligocene to the middle Miocene on the western Tasmania margin as attested by the persistence of laminations and weak bioturbation. The predominance of pelagic carbonates from the earliest Oligocene is unusual at southern high latitudes. The carbonates are likely related to the warm marine influence of subtropical currents transporting heat to the Tasmanian region. This is in sharp contrast with the Ross Sea margin (Site 274), then adjacent to the STR, where biosiliceous microfossils have been predominant since the Oligocene (Hayes, Frakes, et al., 1975).

**Climate and Sedimentation**

No glacial or ice-rafted deposits were found at any of the Leg 189 sites, even sediments from the Oligocene, when the Tasmanian region was still close to Antarctica, suggesting the absence of significant ice cover in nearby East Antarctica. Smectite or kaolinite dominates in most Eocene sediments of the entire Tasmanian region, indicating that warm climates prevailed on emerged adjacent areas of the Tasmanian land bridge and Antarctic margin. An increasing trend toward illite and random mixed-layered clays in the lower Oligocene of Site 1170 on the western STR suggests the development of physical weathering on the adjacent emerged areas, like that in other sectors of East Antarctica (Ehrmann, 1991; Robert and Kennett, 1997). This trend immediately follows the strike-slip activity on the western STR during the transition to the more ventilated biogenic sequence.

The continued presence of common to abundant kaolinite on the western Tasmania margin and the ETP from the lower Eocene to the Pliocene indicates the persistence of relatively warm climates with significant precipitation in the adjacent Australian coastal areas. Episodes of increased kaolinite content on the western Tasmania margin in the lower Oligocene and in the upper to middle Miocene correlate with intervals of interpreted intensified precipitation at midlatitudes. The early to middle Miocene interval immediately preceded the expansion of Antarctic ice at 14–15 Ma (Kennett, 1977). Kaolinite on the ETP increased continuously from the middle Eocene to the Pliocene as Australia moved north to warmer latitudes. Beginning in the Pliocene, an increase in the sediment clay fraction is associated with a mineralogical change to increased illite and kaolinite, a composition very similar to that of the Lord Howe Rise in the Tasman Sea. This pattern suggests the development of a dust supply from arid central Australia, most probably by tropospheric winds associated with cold fronts (Pye, 1987).

There are pervasive alternations of lighter and darker intervals from the Eocene to the Pleistocene in the entire Tasmanian region. Preliminary spectral analyses have been conducted on lightness and magnetic susceptibility data from the west Tasmania margin during a chronologically well-constrained Pliocene–Pleistocene interval. Three important
cycles of ~200, 100, and 40 k.y. may indicate some orbital control on regional sedimentation. High Eocene sedimentation rates on the STR suggest that some variation of the sedimentation at higher frequencies (104–105 yr) might be expected.

**Biostratigraphy**

Leg 189 has provided a wealth of new and exciting biostratigraphic and paleoenvironmental information in a part of the Southern Ocean that is critical to understanding Earth’s Cenozoic history. We drilled five sites in the Tasmanian region, north and south of the Subtropical Convergence, and in the Indian and Pacific Ocean sides of the STR (Fig. F17). The recovered record spans the Late Cretaceous to Quaternary (Fig. F18) but is commonly punctuated by a late Miocene hiatus and a possible Eocene–Oligocene hiatus (Fig. F19). The integrated microfossil record from all five sites will help unravel the southern history of the East Australian Current, which bathed the Pacific Ocean sites, and also the history of the “Proto-Leeuwin” Current, which bathed the Indian Ocean sites. The activity of both of these currents brought warmer waters to the study area, resulting in markedly different faunal associations when compared with other Antarctic circumpolar sites (e.g., Leg 113). The late Miocene hiatus is marked by a strong foraminiferal dissolution event and is restricted to the southernmost sites (Sites 1169, 1170, and 1171), although strong fragmentation of foraminifers was also observed at Sites 1168 and 1172.

The transition from “Greenhouse” to “Doubthouse” is strikingly seen at four of the five sites (Fig. F19). Latest Eocene to earliest Oligocene slow sedimentation (~1 cm/k.y.), which may be continuous or marked by hiatuses, records the history of this dramatic change in Earth’s history. Five major microfossil groups are represented over this interval and provide the opportunity for shore-based collaboration to elucidate the details of this event. At Site 1172, a thick sequence of upper Cretaceous to Eocene fine-grained mudstones of the “Greenhouse” period, often glauconitic and organic rich, contains a continuous dinocyst record. Sporadic calcareous nanofossils and planktonic and benthic foraminifers through this interval will provide age control, as well as paleodepth information.

The planktonic foraminiferal distribution reflects the northward drift of Australia during the Cenozoic. Because of the southern location of Australia during the Paleogene, the subantarctic zonal scheme was used in place of the traditional temperate scheme. This temperate scheme was appropriate for the late Paleogene and Neogene. In addition, the Neogene faunal diversity, preservation, and phylogeny reflect changing paleoceanography throughout the “Icehouse” period. The expanded Oligocene and Neogene section of the two northern sites (with sedimentation rates between 1.7 and 4.3 cm/k.y.), and of Site 1168 in particular, means that a standard biostratigraphic section can be established for the shelf and onshore exposures to the north (this applies also to the other microfossil groups). The *Globoconella* group is widely distributed through the Neogene section and phylogenetic studies coupled with paleoceanographic results should provide an improved planktonic foraminiferal biostratigraphy for the region. The low-diversity planktonic foraminiferal assemblages of the Late Cretaceous and Paleogene are generally very well preserved, but their abundances are low.

Benthic foraminifers at all sites show a clear change between neritic water depths in the Cretaceous to Eocene interval and deeper waters of
the Oligocene and Neogene. At all sites except one (Site 1168), subsidence across the Eocene/Oligocene boundary appears to be a rapid event, whereas the trend at Site 1168 is more gradual. However, this site is the only one with an expanded Oligocene sequence. Eocene benthic foraminiferal assemblages indicate a more pronounced regional influence, whereas low-resolution sampling in the Oligocene and Neogene section suggests that the general trends at all sites are similar for the Neogene, with only Site 1168 showing clear differences in the Oligocene.

The Neogene standard nannofossil zonal scheme and the Paleogene nannofossil zonation for the Southern Ocean were successfully applied to Leg 189 sites to provide some of the most useful subantarctic temperate biostratigraphic records to date. In particular, the Oligocene to Pliocene interval is among the most detailed of the similar latitude Southern Ocean sites. This sequence will serve as an important reference section for the Southern Hemisphere. Eocene through lower Oligocene nannofossil assemblages at Leg 189 sites show warmer water characteristics than comparable paleolatitude sites in other sectors of the Southern Ocean (Sites 512, 513, 699, 703, and 747), which reflects the activity of the warm-water Proto-Leeuwin and the East Australian Currents.

Oligocene to Quaternary diatoms are abundant at all sites drilled during Leg 189, except Site 1168, and will be used to construct the first calibrated Oligocene–Holocene diatom biostratigraphy south of Australia. In particular, high-resolution biostratigraphy looks especially promising for Sites 1170 and 1171. Integration with other Paleogene and Neogene diatom biostratigraphies being developed from recent ODP legs to the Southern Ocean (e.g., Leg 177) will contribute to a scheme applicable to northern parts of the Southern Ocean. Neritic diatoms are prolific in upper Eocene and lowermost Oligocene sediments at Sites 1170, 1171, and 1172. In conjunction with dinocysts, they will be useful for reconstructing paleoenvironmental conditions across the Eocene/Oligocene boundary including productivity (trophic status), water energy levels, relative salinity, and sea level for both the Indian and Pacific Oceans. During the early Oligocene, the marked floral changes and increased diversity within Sites 1170, 1171, and 1172 imply increasing oceanic influence and productivity. The Neogene diatom floras indicate fluctuations in the influence of warm temperate and subantarctic water masses over Site 1170, heralding meridional shifts in the position of the Subtropical Convergence as well as the presence of the Proto-Leeuwin Current. At Site 1172, similar fluctuations may signal variations in the influence of the East Australian Current.

Radiolarians are well represented at all sites except Site 1168, although diversity varies through the sequences. The subantarctic radiolarian biostratigraphic sequence from the middle Eocene through Pleistocene is unique and will provide an important new radiolarian zonation. This subantarctic scheme will provide a correlation between tropical and Antarctic biostratigraphies even though there is a near absence of tropical and cold-water age-diagnostic species in the Tasmanian region. The radiolarian faunas from Leg 189 also provide an insight into radiolarian evolution.

The dinoflagellate-cyst studies have provided a number of important new observations. The first well-calibrated Neogene and Oligocene dinocyst record of the Southern Ocean was discovered at Site 1168. These microfossils are extremely abundant and, with sporomorphs, are common in the Upper Cretaceous to lowermost Oligocene successions. Together with palynofacies analysis, there is a great potential for well-
calibrated high-resolution biostratigraphy. Dinoflagellate cysts appear to provide the sole biostratigraphic means for age assessment of the critical uppermost Eocene–lowermost Oligocene interval (the so-called “barren green sands”), although sporomorphs are present as well. Together with the diatoms, the palynomorphs will allow detailed paleoenvironmental interpretation. Postcruise paleoenvironmental and paleoclimatological studies, including “land-sea correlation” may be possible on time scales down to <20-k.y. cycles. Also, the first well-calibrated Paleogene dinocysts and sporomorph records from the Southern Hemisphere should result from postcruise studies. Cores have yielded the best imaginable material to study the variability of dinocyst morphology, notably within the Deflandrea phosphoritica and Areosphaeridium diktyoplokum–Enneadocysta partridgei groups.

Future stable isotopic studies on planktonic foraminifers, together with quantitative analysis of diatoms, nannofossils, and dinocysts, should be useful for detailed reconstruction of the sea-surface paleotemperatures, paleoproductivity, and other paleoenvironmental parameters, such as fluctuations in the position of the Subtropical Convergence. An outstanding biostratigraphic contribution resulting from Leg 189 will be an integrated zonation scheme, including the six microfossil groups for the Oligocene to the Quaternary for this sector of the Southern Ocean.

**Paleomagnetism**

Paleomagnetism tends to be a difficult profession during carbonate legs. However, during Leg 189 we were fortunate enough to generate some magnetostratigraphy at all sites, and at Sites 1170, 1171, and 1172 the paleomagnetic record was sufficient for construction of useful age-depth plots. Our work is described in terms of its three main aspects: (1) magnetostratigraphy, (2) rock magnetism, and (3) investigation of magnetic overprints and measurement difficulties.

**Magnetostratigraphy**

Magnetostratigraphic interpretation of the paleomagnetic record at Sites 1168, 1169, and 1170 was restricted to the Pliocene–Pleistocene and late Miocene. At Sites 1171 and 1172, the paleomagnetic records were adequate to generate a Neogene age-depth plot independent from biostratigraphic datums. At Site 1172, magnetostratigraphy was established down to the middle Miocene. Although the quality of the magnetic record deteriorated in older intervals, a relatively complete magnetostratigraphy was achieved, particularly across the Eocene/Oligocene boundary. Unfortunately, at both sites the interpretation of the Eocene inclination record was problematic, which led to the development of an approach based upon the sign of the z-component. This approach generated distinctive magnetostratigraphic boundaries, where they were almost totally obscured in the inclination record. The magnetostratigraphy for Leg 189 is summarized in Table T3, which displays the observed boundary chron depths at the various sites. Where there was more than one core at a given depth at a given site, the depths are taken from the best magnetostratigraphic record.
Rock Magnetism

Throughout Leg 189, rock magnetism studies have revealed a remarkable homogeneity of magnetic material. Most discrete samples had anhysteretic remanent magnetization (ARM) intensities of order $10^{-3}$ A/m and isothermal remanent magnetization (IRM) intensities one order greater. We interpret the ARM/IRM ratio as typical for a detrital source. However, at Site 1168 this ratio was higher, suggesting that the magnetic record was carried in fine, single-domain grains probably of biogenic origin. At Sites 1170 and 1171, attempts to correlate magnetic properties (ARM/IRM, IRM 20/IRM, and IRM 500–IRM 200/IRM 500 ratios) with lithostratigraphic units were unsuccessful. Throughout much of the Cenozoic, magnetic properties were very similar and seem to reflect a similar source, as if the magnetic carriers were not influenced by environmental changes. However, some changes were weakly correlated with lithology, and the origin of the hard carriers observed in some sections remains to be determined from shore-based studies.

Measurement Techniques

The techniques used during this leg varied somewhat from the standard methods. For the most part, we measured unsplit sections instead of archive-half sections. This was performed prior to the multisensor track (MST) measurement. Because the paleomagnetic measurement is faster than the MST track, the paleomagnetic analysis of the unsplit section was conducted in dead time, and thus, core flow was improved. A long-standing problem in the paleomagnetism of ODP-recovered sediments, and in particular in results from magnetically weak sediments such as carbonates encountered during this leg, has been the bias toward the “0°” declination reading. The analysis of the drift of the 2G cryogenic magnetometer indicates that one possible explanation for this phenomenon in very weakly magnetized sediments is improper application of drift corrections, although this needs to be investigated in more detail on shore. The use of nonmagnetic core-barrel assemblies permitted comparisons between magnetic results from standard and nonmagnetic assemblies, which did not appear to make a major difference to the magnetization of recovered cores, although further analysis on shore is also required.

In summary, during Leg 189 we encountered the usual difficulties of carbonate legs, but considerable magnetostratigraphy was achieved and aspects of measurement and analysis techniques have been improved. Of particular note is the measurement of unsplit sections to increase intensities and reduce potential overprinting from splitting and the utilization of the intensity of the $z$-component to interpret the magnetostratigraphy.

Physical Properties and Downhole Measurements

High-resolution (2–3 cm) whole-core gamma-ray attenuation (GRA) bulk density and magnetic susceptibility data collected on the MST show two distinct Cenozoic units: (1) an upper unit marked by very low magnetic susceptibility values and relatively low bulk density associated with the Oligocene to Quaternary pelagic carbonate deposits and (2) a lower unit with high and variable magnetic susceptibility values and
relatively higher and more variable bulk density associated with the Cretaceous to late Eocene shallow-water siliciclastic deposits (Fig. F20).

The bulk-density data show the first-order effect of downhole compaction and dewatering, with lithologic variability superimposed on this trend. In addition, the bulk-density values in the lower unit are artificially low as a result of XCB and RCB coring techniques that recover a smaller diameter core. The magnetic susceptibility profiles, on the other hand, provide a clearer picture of the change from shallow-water siliciclastic sedimentation to more open ocean pelagic biogenic sedimentation. Lithologic variability, in particular the variation in carbonate and siliciclastic content, drives the first-order changes in the magnetic susceptibility data.

The high-resolution physical properties data suggest that the transition from shallow-water siliciclastic sedimentation to a more open ocean biogenic pelagic character is locally variable. The southern South Tasman Rise site (Site 1171) shows the first effects of this transition in the Eocene, although a full open-ocean carbonate biogenic sedimentation pattern is not present until the upper Oligocene/lower Miocene. The western South Tasman Rise site (Site 1170) changes to open-ocean carbonates in the upper Eocene/Oligocene. The more northern East Tasman Plateau (Site 1172) and Western Tasmania Margin (Site 1168) sites are marked by abrupt changes to open-ocean carbonates in the lower Miocene.

Both data sets exhibit sedimentary cycles superimposed on the first-order lithologic and depth-related changes. Shipboard biostratigraphic and paleomagnetic results suggest that the period of these cycles range from ~400 to 20 k.y. Detailed postcruise sediment geochemical, biostratigraphic, and paleomagnetic studies are required to differentiate the changing effects of terrigenous supply and biogenic production that influence the period of these sediment cycles and to quantify the evolution of sedimentation patterns (cyclicity) during the Cenozoic.

Downhole logging was conducted at four of the sites drilled during Leg 189 (Sites 1168, 1170, 1171, and 1172). The sequences logged included a range of siliciclastic and biogenic sediments deposited in a variety of Late Cretaceous to the late Neogene sedimentary environments. The results from all sites show that there are two distinct Cenozoic logging units: (1) an upper unit characterized by low natural gamma, magnetic susceptibility, resistivity, and an ~4 photoelectric value associated with the Oligocene to Quaternary pelagic carbonate deposits and (2) a lower unit with higher natural gamma, higher magnetic susceptibility, and lower photoelectric values associated with the Paleocene to late Eocene shallow-water siliciclastic deposits (Fig. F21).

Log parameters in the upper unit are fairly uniform with only small variations apparent in magnetic susceptibility, natural gamma, density, and resistivity indicating that relatively homogeneous, carbonate-rich, pelagic sediments have accumulated since the Oligocene. The small fluctuations in the natural gamma and susceptibility logs imply that, despite the predominance of pelagic carbonates, variations in the sediment’s terrigenous content occurred throughout the Neogene. Minor changes in the terrigenous component could result from variations in the supply and delivery of terrigenous material to the site or, alternatively, may represent changes in the overlying production of biogenic carbonates, which dilute a relatively constant terrigenous supply. Discriminating between these various influences, each of which is related to different physical mechanisms with their own relationship to cli-
mate changes, will require detailed postcruise sediment geochemical studies.

In contrast to the relative stability of log parameters in the Neogene pelagic sequences, pronounced variability is evident in downhole logs within the underlying shallow-water Paleocene to Eocene siliciclastic deposits. This lower sequence is characterized by a general increase in the downhole natural gamma logs with depth, suggesting that the sediment’s terrigenous fraction increases with age at every site, although the trend is most pronounced at the STR Site 1171. Likewise, the general increase in U-spectral gamma logs with depth suggests that the shallow-water siliciclastic Paleogene deposits have higher organic carbon content than the overlying open-ocean Neogene deposits. The Th/U > 2 suggests that the Paleogene depositional environment was dysoxic to oxic and less ventilated than the overlying pelagic carbonate sequence. Superimposed on this general trend of increasing natural gamma values with depth are intervals containing higher frequency cyclic variations in the spectral gamma, magnetic susceptibility, and resistivity logs at Sites 1170, 1171, and 1172. The regional persistence of these Th spectral gamma and magnetic susceptibility cycles suggests a common influence on sedimentation, either through changes in sea level or regional climate, which influenced sediment supply and/or delivery. Shipboard biostratigraphic results suggest that the period of these sediment cycles is near 20 or 40 k.y. using nannofossil and dinocyst datums, respectively.

The transition interval between the relatively homogeneous upper log units and the highly variable lower log units varies in thickness by site, occurring abruptly at Sites 1171 and 1172 but more gradually at Site 1168. In addition, correlative peaks in the density, resistivity, PEF, and K spectral gamma logs, associated with glauconite-rich sediments (typical of sediment-starved environments) are common in upper Eocene sediments just below the transition to the overlying deeper, open-ocean carbonate deposits.

Geochemistry

The drilling of five sites in the region off Tasmania, in particular the four Sites 1168, 1170, 1171, and 1172, provided unique insights into both regional and temporal variation in organic and interstitial water geochemistry. The results of the organic geochemical characterization of sediments cored during Leg 189 have led to the following salient observations. First, a two-tiered carbonate distribution is characteristic of Sites 1170, 1171, and 1172. In this distribution, Paleogene sediments are generally carbonate poor, whereas Neogene sediments are carbonate rich. Second, the transition from Paleogene carbonate-poor to Neogene carbonate-rich sediments appears to be mostly abrupt, except at Site 1168, where it is gradual. Third, an antithetic relationship exists between carbonate and TOC content. In this relationship, Paleogene sediments usually contain >0.5 wt% TOC, whereas Neogene sediments are relatively free of organic matter. Fourth, organic matter type determined primarily by Rock-Eval pyrolysis and paleosalinity characterizations using C/S ratios provide a basis for intersite geochemical facies correlation from site to site. The facies show distinct, and perhaps important, changes at the Paleocene/Eocene boundary, in the middle Eocene, and near the Eocene/Oligocene boundary. Fifth, at Sites 1168, 1170, and 1171, methane contents obtained from headspace gas mea-
measurements show an abrupt increase in the organic carbon-containing Paleogene sediments.

Paleogene sediments with relatively high TOC and low CaCO₃ contents exist at Sites 1168, 1170, 1171, and 1172 (Fig. F22). These sediments are bioturbated (see “Lithostratigraphy,” p. 32) and have higher natural gamma values (Fig. F21), in particular Th/U ratios mostly ≥2 (see “Physical Properties and Downhole Measurements,” p. 38). These characteristics indicate dysoxic to oxic conditions on the seafloor during deposition. Most of the relatively high TOC–low CaCO₃ sediments may have undergone enhanced burial efficiency of organic matter associated with more rapid siliciclastic sedimentation. The generally poorer ventilation of the waters during this time may have promoted high TOC–low CaCO₃ sediments relative to the Neogene.

The high carbonate content of Neogene sediments reflects dominance of calcareous nanofossils; foraminifers are secondary in importance (see “Biostratigraphy,” p. 35). The upward increase in carbonate content at all sites during Leg 189 is a consequence of a change from shallow-marine to pelagic open-ocean conditions. The low organic carbon content of these carbonate-rich sediments suggests deposition through a well-mixed water column to a well-oxygenated seafloor. The transition from carbonate-poor to carbonate-rich sediments appears to be relatively abrupt at Sites 1170, 1171, and 1172, although higher resolution sampling at Site 1172 demonstrates that the carbonate content changes through ~10 m of section. This observation suggests that higher resolution sampling across this boundary at Sites 1170 and 1171 may better define the nature of this carbonate-rich/carbonate-poor boundary. Specifically, the presence of a condensed section can be inferred if the carbonate content increases gradationally across the boundary, whereas the presence of an unconformity can be considered where an abrupt change in carbonate content is observed. At Site 1168, the change from siliciclastic to carbonate sedimentation is gradational, because terrigenous sedimentation was more continuous.

The similarity of geochemical facies between sites is significant because it suggests regional-scale changes in seafloor and water-column conditions. Upper Paleocene–lower Eocene sediments encountered at Sites 1171 and 1172 contain elevated TOC content and variations in C/S and hydrogen index values indicative of fluctuations between terrestrial and marine inputs (Fig. F22). These characteristics suggest rapidly changing environmental conditions across the Paleocene/Eocene boundary in the Tasmanian region. A middle Eocene episode of elevated organic carbon burial was widespread in shallow-marine environments. Correlating to this time, a clear gradient from terrrestrially influenced to dominantly marine organic matter preservation is observed from Site 1170 to Sites 1171 and 1172. These observations may reflect deposition at Site 1170 within the Australo-Antarctic Gulf, whereas Sites 1171 and 1172 were more strongly influenced by the Paleogene Pacific Ocean.

The highest organic carbon contents observed during Leg 189 are from upper Eocene sediments at Site 1168. Here, TOC content exceeds 5 wt% and is nearly wholly terrestrial in origin. Such characteristics were not encountered at any of the other sites and likely reflect the proximity of Site 1168 to hinterland source regions, as well as the site location well within the restricted Australo-Antarctic Gulf. However, upper Eocene sediments at Sites 1168, 1170, and 1171 share a C/S record of brackish water conditions before the transition from carbonate-poor to carbonate-rich sedimentation. This signal is difficult to re-
solve within a setting of overall water deepening. Perhaps, the seaway conditions were deeper, but climatic fluctuations were sufficient to cause episodes of “freshening” of the water column and/or sediment pore fluids. Alternatively, the brackish water signature in C/S values may actually represent unrecognized periods of decreased pyrite formation. In either case, more analyses will be needed to understand the significance of the geochemical record from this interval.

Headspace gases at all Leg 189 sites are best characterized as biogenic, although thermogenic inputs were observed at the base of most holes. Rock-Eval pyrograms from Paleogene sediments often display a double S₂ peak character, suggesting the presence of bitumen. $T_{\text{max}}$ values obtained by Rock-Eval pyrolysis indicate that organic matter is mostly immature, although values characteristic of the “oil window” were recorded at depth in most holes. Methane gas content is closely tied to pore-water sulfate concentrations at Sites 1168, 1170, 1171, and 1172 (Fig. F23), which in turn is closely tied to the lithostratigraphic separation between carbonate-rich and carbonate-poor sediments. The onset of methanogenesis immediately beneath the sulfate reduction zone exhibits the characteristics of microbially driven diagenetic depth zonation. In this model, carbonate-poor Paleogene sediments contain sufficient organic matter for complete sulfate reduction, whereas the sulfate reducers in carbonate-rich Oligocene and Neogene sediments inhibit methanogens. At Site 1172, however, the sulfate reduction process is likely inhibiting methanogenesis in the organic carbon-bearing Paleogene sediments. This observation is unusual because the TOC content of these low-gas sediments appears to be sufficient to have already driven sulfate concentrations to zero.

One of the surprising discoveries of the Leg 189 interstitial water geochemistry program was the presence of regionally extensive low-chloride (Cl⁻) pore fluids in the older sediments throughout the region, including on the west Tasmania margin (Site 1168), the STR (Sites 1170 and 1171), and the ETP (Site 1172) (Fig. F23). In general, the fresher pore waters are located in the older part of the cored interval but are in different aged sediments and are not restricted to specific lithologies. These fresher fluids are manifested in the Cl⁻ profiles by multiple distinct maxima and minima rather than smoothly decreasing values. Minimum Cl⁻ values at the four sites range from 486 to 440 mM, a 13%–21% decrease relative to the mean seawater value (559 mM). At three of the sites, pore-water freshening coincides with the onset of methanogenesis; however, low Cl⁻ fluids were encountered at Site 1172, where only trace quantities of methane are present (Fig. F23).

At present, the origin of the low-Cl⁻ fluids is enigmatic. Low Cl⁻ values in marine pore waters have been observed in environments ranging from accretionary prisms to passive continental margins. One possible external source of low-Cl⁻ fluids in passive continental margins is the advection of meteoric waters from the continent (e.g., Austin, Christie-Blick, Malone, et al., 1998). However, the geographic separation of the sites (Fig. F3) and the general geologic setting (see “Geologic Setting,” p. 6, in “Introduction”) make it improbable that continental recharge occurred here.

Possible internal sources that may provide low-Cl⁻ fluids include (1) gas hydrate dissociation; (2) dehydration reactions of hydrous minerals, such as clays and biogenic opal; (3) clay membrane ion filtration (e.g., Kastner et al., 1991; Hesse and Harrison, 1981; Paull, Matsumoto, Wallace, et al., 1996); and perhaps (4) connate fluids. Gas hydrate dissocia-
tion is a common cause of such profiles in continental margin settings. However, crude estimates of the base of the gas hydrate stability zone (GHSZ) at Sites 1168, 1170, and 1171, assuming a pure methane and seawater system, indicate that the low-Cl\textsuperscript{–} fluids are below the stability zone. The depth of the hydrate stability zone will be sensitive to the chemistry of the pore fluids and incorporation of other gases into the hydrate structure (Dickens and Quinby-Hunt, 1997; Sloan, 1998). Therefore, a more rigorous calculation of gas hydrate stability may extend the depth of the stability zone. However, the presence of low-Cl\textsuperscript{–} fluids at Site 1172, with only traces of methane present, appears to eliminate gas hydrates as a possible mechanism, at least at Site 1172.

We also currently cannot eliminate connate fluids as the possible source of fresher fluids. However, the distinct Cl\textsuperscript{–} maxima and minima should have been smoothed by diffusional processes that are clearly at work with other interstitial water constituents (Fig. F23). In fact, the jagged nature of the Cl\textsuperscript{–} profiles suggests that the emplacement of fresher fluids has occurred relatively recently. Clay mineral reactions are a well-known source of fresh fluids, and clay content increases in the older part of the sedimentary succession (see “Lithostratigraphy,” p. 32). Although reaction kinetics are also important, previous research, both experimental and natural observations, indicates that dehydration reactions (e.g., alteration of smectite) occur at elevated temperatures of 80°C or higher (e.g., Perry and Hower, 1972; Velde, 1983). Downhole temperature measurements made during Leg 189 indicate geothermal gradients of ~50°–60°C/km, and all sites were drilled <1 km deep. Thus, the origin of these regionally extensive fresher pore fluids remains unresolved, and postcruise isotopic analysis of the interstitial waters will be required to better understand these diagenetically and/or paleoenvironmentally important fluids.

In addition to the low-Cl\textsuperscript{–} fluids, pore-water profiles are characterized by reactions involving the alteration of silicate minerals, carbonate recrystallization, and organic matter degradation (Fig. F23). Alteration of silicate minerals, within and below the cored section, may have lead to covarying decreases in Mg\textsuperscript{2+} and K\textsuperscript{+} and increases in Li\textsuperscript{+} within the pore fluids. The smooth, diffusional Mg\textsuperscript{2+} and K\textsuperscript{+} profiles observed at all sites are likely the result of uptake in reactions below the cored interval. Carbonate recrystallization is most pronounced in the Oligocene and Neogene pelagic carbonates, resulting in increases in interstitial Sr\textsuperscript{2+}. The thinnest carbonate sequence (Site 1171) has the lowest Sr\textsuperscript{2+} concentrations with the thinnest interval of elevated Sr\textsuperscript{2+} (cf. Sr\textsuperscript{2+} to carbonate profiles in Fig. F22). As described above, organic matter reactions are most active in the thick, organic-rich Eocene sediments in the lower part of the cored intervals, which may result in differing sulfate gradients (i.e., thicknesses of the sulfate reduction zone) as sulfate is rapidly depleted in the organic-rich Eocene sections.

**DISCUSSION AND CONCLUSIONS**

**Regional Sedimentation**

The sedimentary succession in the Tasmanian region generally records three major phases of sedimentary deposition:

1. Paleocene (Maastrichtian in one site) to early upper Eocene rapid deposition of shallow-water siliciclastic sediments during rifting
between Antarctica and Southeast Australia, at a time of minimal or no connection between the southern Indian and Pacific Oceans.

2. A transitional interval of slow sedimentation, with shallow-water upper Eocene glauconitic siliciclastic sediments giving way suddenly to lowermost Oligocene pelagic carbonates (often clayey initially). The transition was caused by the activation of bottom currents during the late Eocene as the Tasmanian Gateway opened and deepened during early drifting. Cooling reduced precipitation and the flow of siliciclastic sediment, and currents swept the shelves. Sedimentation no longer kept pace with subsidence, and pelagic carbonate deposition was established in the early Oligocene.

3. Oligocene through Quaternary deposition of pelagic carbonates in increasingly deep water and open ocean conditions predominated as the Southern Ocean developed and expanded with the northward flight of the STR and the Australian continent. The sedimentary sequence seems to record an integrated history of interplay between decreasing continental influence, rifting and subsidence of the STR, Antarctic Circumpolar Current development and Antarctic cooling, and other related factors.

In general, sedimentation rates throughout the region changed dramatically in relation to these distinct phases of sedimentation. These were rapid (~10 cm/k.y.) during the siliciclastic sedimentation of the early rifting phase of the late Paleocene to early late Eocene, slow to condensed during the Eocene–Oligocene transition, when more glauconitic sediments were deposited, and generally slow during the biogenic sedimentation from the earliest Oligocene to the present. There were periods of minimal late Oligocene and late Miocene sedimentation or erosion.

Considerable thickness variation is evident for different time periods among the sites. The two major sediment types, pelagic carbonates of the Oligocene and Neogene and the shallow-water siliciclastic mudstones of the Paleogene and Late Cretaceous, are dealt with separately below. In regard to the pelagic carbonates, the Quaternary is thickest at the two southern sites (Sites 1170 and 1171). The Pliocene is thickest at the western sites on the STR and especially thick at Site 1169, which was protected from east-flowing current scour by its great depth and the ridge of the TFZ. The Miocene is affected by the onset of the strong Antarctic Circumpolar Current, with the thickest and most complete section found in the protected northern Site 1168. The other northern site (1172) has a fairly complete but thinner section. The lower Miocene is especially thin at the southern Sites 1169, 1170, and 1171, probably because of current scouring. The Oligocene, too, was strongly affected by the Antarctic Circumpolar Current and/or the East Australian Current, with the protected northern Site 1168 as the only one with a thick and reasonably complete sequence (Figs. F16, F17).

The upper Eocene siliciclastic mudstones are thin everywhere, apparently because fine-grained sediments were swept away by the newly forming shallow-water Antarctic Circumpolar Current at all sites. In contrast, the lower and middle Eocene are thick everywhere because siliciclastic supply was rapid and there was little current erosion. The same interpretation probably applies to the Paleocene at the southern Site 1171, whereas there is little Paleocene at the northeastern Site 1172. The uppermost Cretaceous mudstones penetrated at Site 1172 may be quite thick judging from seismic reflection profiles.
**Tectonic Evolution**

During the Mesozoic, the Tasmanian region was well within east Gondwana, and although the locations of all the sites eventually remained part of Australia, the four deep sites are all on different blocks of continental crust that behaved somewhat differently as Gondwana fragmented. According to the plate tectonic reconstruction of Royer and Rollet (1997), during the mid-Cretaceous (Fig. F5) the locations of Sites 1169 and 1170 were close together on the Antarctic side of the northwest-southeast strike-slip zone along which Australia was moving northwest relative to Antarctica, here named the Tasmania-Antarctic Shear Zone (TASZ). Across the TASZ were the locations of Sites 1168 and 1171, some 600 km apart. Site 1172 was ~300 km east of Site 1170 and well away from the rift zone.

An east-west rift along the southern margin of Australia and the northern margin of Antarctica, and slow northwest-southeast separation, may have begun as early as the Late Jurassic (Willcox and Stagg, 1990). This rift continued eastward in the Otway, Bass, and Gippsland Basins between Australia and Tasmania. Crustal thinning and subsidence occurred along the developing east-west rift, which was filled with thousands of meters of nonmarine Lower Cretaceous sediments. From the mid-Cretaceous (95 Ma) to the middle Eocene (43 Ma), Australia moved northwest relative to Antarctica at a slow rate of ~10 m/m.y. As the east-west rift widened into the Australo-Antarctic Gulf, the sea transgressed from the west depositing shallow-marine and deltaic Late Cretaceous to Eocene sediments. In the Late Cretaceous (75 Ma), the Tasman Sea began to form and rifting in the Bass Strait failed.

In the Tasmanian region, the TASZ terminated the east-west rift. The block east of the TASZ, consisting of southeast Australia, Lord Howe Rise, and Campbell Plateau, moved northward along the shear zone. Some crustal thinning occurred along the TASZ, with possible deposition of Early Cretaceous sediments. By the Late Cretaceous, the TASZ was subsiding steadily, marine transgression took place through the Gulf from the west, and shallow-marine deltaic sediments began to be deposited in the extreme eastern part of the Australo-Antarctic Gulf. This phase of deposition continued into the Eocene.

In the Late Cretaceous (75 Ma), the Lord Howe Rise, Campbell Plateau, and the ETP all began to move away from Australia and Antarctica to the east-northeast (relative to Australia). At 65 Ma, in the latest Cretaceous, the ETP (with Site 1172) stopped moving with the other blocks, but a legacy of rifting before that movement is its thinned crust and the partially oceanic depression between the ETP and what became the STR. Results from Site 1171 showed that strike-slip movement within the central and eastern STR (e.g., on the Balleny Fracture Zone) occurred during a short period in the late Paleocene, when spreading began south of the STR. This agrees with the plate tectonic reconstruction of Cande et al. (2000), which shows that from the late Paleocene east-west spreading extended from south of the STR and north of the Transantarctic Mountains (TAM) across to New Zealand. This interval marks the beginning of the uplift of the TAM (Fitzgerald, 1992). However, evidence from the 1999 Cape Roberts drilling, in the western Ross Sea, indicates that Victoria Land Basin first formed by ~3000 m of rapid subsidence east of the TAM at ~34 Ma, close to the Eocene/Oligocene boundary (Cape Roberts Science Team, 2000), suggesting that much of the TAM uplift may have occurred at that time.
This tectonic scenario for Antarctica seems to have been reflected in the structurally interconnected Tasmanian region. If late Paleocene uplift of the TAM did occur, this uplift would have corresponded to the period of strike-slip movement, and associated vertical displacement, on the central and eastern STR. The end of this movement corresponds to the onset of spreading between the TAM and the STR, which separated the strike-slip faults within most of the STR from tectonic movement in Antarctica. However, early Oligocene collapse of the continental margins everywhere in the Tasmanian region, documented in part by Leg 189 drilling, coincides precisely with the age of formation of the Victoria Land Basin on the conjugate Antarctic margin (~34 Ma). A causal relationship between these events appears probable, but determining that relationship awaits postcruise research.

The Site 1168 region was part of the Tasmanian block throughout its Cretaceous and Cenozoic history and within the Sorell Basin depocenter formed by crustal thinning along the TASZ. The Sorell Basin was fully separated from the conjugate eastern end of the Wilkes Land Basin in Antarctica once large quantities of oceanic crust began to form in the easternmost Australo-Antarctic Gulf during the middle Eocene (43 Ma). In regard to the oldest seafloor spreading in this region, Pyle et al. (1995) obtained Ar-Ar dates of 60.7 Ma from basalt at the base of nearby DSDP Site 282 on thinned continental crust, but doubts remain about this date because of the extent of alteration of the basalt. Royer and Rollet (1997) suggest the presence of some oceanic crust as old as Chron 24 (55 Ma). Like the basins to the north, the Sorell Basin subsided throughout the Cretaceous and Cenozoic and was filled with thick shallow-marine Upper Cretaceous to Eocene deltaic sediments derived largely from Tasmania. Strike-slip faulting, active into the Paleocene, cut the basin into a number of subbasins and ridges in which Site 1168 is located. In the earliest Oligocene, the Sorell Basin subsided rapidly into deep water and the deposition of pelagic carbonate commenced. This observation has also been made to the northwest in the Otway Basin. In both cases, the subsidence appears to have been about hinge lines near the present coastlines. The cause of the initial rapid subsidence remains unclear, but it was a regional event. Subsidence may have resulted from the final clearance of southeast Australia (the southwestern tip of the STR) from Antarctica (Wilkes Land) near the Eocene/Oligocene boundary (Fig. F6). Site 1168 contains a remarkably continuous Eocene to Holocene sequence, but with a clear transition from siliciclastic deposition in the Eocene to pelagic carbonate deposition in the early Oligocene as the margin sank rapidly.

According to Royer and Rollet (1997), Site 1170 was part of the Antarctic block (Wilkes Land) in the early Late Cretaceous, separated from Southeast Australia by the TASZ. After collision with the central STR block in the latest Cretaceous (66 Ma), the western STR block formed, on which Site 1170 is located. This block began to separate from Antarctica by strike-slip motion, with the TASZ transferring to the block’s western side. By the latest Paleocene, the STR block was firmly welded to southeast Australia. During the middle Eocene (43 Ma), the onset of north-south fast spreading in the Australo-Antarctic Gulf increased the rate of movement along the TASZ (which was now the TFZ) to ~30 m/m.y. At the same time, fast spreading started south of the STR. Much of this block is covered by the Ninene Basin, which is cut by Cenozoic strike-slip faults into subbasins and ridges. The basin is filled at least in part by fairly thick Upper Cretaceous to Eocene prograded shallow-marine siliciclastic sediments. This western block was substantially
thinned by tectonism and now lies much lower than the adjacent central block of the STR. Site 1170 is located only 10 km from the eastern side of the Ninene Basin (Exon et al., 1997b), where the basin abuts against the north-south fault (and modern fault scarp) that marks the suture with the central block.

During the earliest Oligocene, Site 1170 and the Ninene Basin subsided rapidly into deep water, as at Site 1168. The initial fast subsidence is a regional event involving at least Southeast Australia and the Victoria Land Basin in Antarctica. The final clearance of the western block from Antarctica near the Eocene/Oligocene boundary probably had an effect at Site 1170. The unusually thin upper Oligocene sequence may have been caused by increased current erosion, caused by shallowing as the spreading axis, with its heat source, passed 100 km to the west (~26 Ma). Site 1170 contains a less complete Upper Eocene to Holocene sequence than Site 1168 because of the generally greater current activity caused by the site’s greater proximity to the Tasmanian Gateway between the STR and Antarctica and the associated Antarctic Circumpolar Current. The transition from Eocene siliciclastic sediments to lowermost Oligocene pelagic carbonate, as the basin sank rapidly, was much sharper than at Site 1168. This more transitional change at Site 1168 was probably caused by the ongoing supply of siliciclastic sediments from the high hinterland of Tasmania.

During the Early Cretaceous, the southernmost Site 1171 was located on the east Gondwana block consisting of Australia, the Lord Howe Rise, and the Campbell Plateau across the strike-slip TASZ from Antarctica. Some Early Cretaceous sediments must have been deposited along the TASZ, but there is no evidence of them near Site 1171. According to Royer and Rollet (1997), the central and eastern blocks of the STR separated from the Tasmanian block in the early Late Cretaceous (95–83 Ma). Site 1171 is located near the boundary between the two blocks, which “jostled” as they moved. As Australia moved northwest, the two blocks were “braked” by Antarctica until the latest Cretaceous (65.6 Ma), with 150 km of stretching between this and the Tasmanian block forming the South Tasman Saddle. Strike-slip basins and ridges developed within the two STR blocks, but there was only limited thinning of these cratonic blocks. Seismic profiles suggest that the basins were filled by prograded Upper Cretaceous and Paleocene sediments (probably shallow marine) derived from the subaerially exposed ridges and along the basins from higher areas to the north. During the Late Cretaceous, at 75 Ma, seafloor spreading started to the east with the Campbell Plateau and the ETP separating from the composite block and moving east-northeast relative to Site 1171. The continental crust of the blocks was thick, so subsidence was limited.

The timing of the initiation of seafloor spreading to the south of Site 1171 is open to interpretation, as profiles with magnetic anomalies are limited and the older anomalies are close together and questionable. Royer and Rollet (1997) reliably identify Anomaly 20 (45 Ma), questionable identify Anomaly 24 (55 Ma), and very doubtfully identify Anomaly 31 (67 Ma). Fast spreading clearly began in the middle Eocene (43 Ma). Pyle et al. (1995) obtained Ar-Ar dates of 64.2 Ma from the basalt at the base of DSDP Site 280 on nearby oceanic crust, but because of its alteration, doubts remain about this date. Further information on the breakup comes from Site 1171 itself, which lies in a small north-south basin bounded to the east by an arm of the Balleny Fracture Zone, the boundary between the central and eastern STR blocks. From this site, seismic and palynological data show an unconformity between very
broadly and gently folded sediments of Cretaceous to late Paleocene (58 Ma) age and onlapping and flat-lying early Eocene sediments. This shows that much of the movement within continental crust along the Balleny Fracture Zone (which has been active in oceanic crust ever since) was confined to the period between 58 and 54 Ma (i.e., latest Paleocene–55 Ma). The end of this episode of strike-slip faulting and associated folding agrees with the Anomaly 24 identification above, confirming that final separation south of the STR (from Wilkes Land) was in the late Paleocene.

During the earliest Oligocene, Site 1171 and the central STR block subsided into deep water, similarly to Sites 1168 and 1170. The amount of subsidence was less than at those sites because of the greater crustal thickness at Site 1171. The likely cause of at least part of the early Oligocene subsidence (contemporaneously with that of the margins elsewhere in southeast Australia and the Victoria Land Basin) is again the final clearance of the attached western STR block from Antarctica. Site 1171 contains a much thinner and less complete upper Eocene and Oligocene sequence than Sites 1168 and 1170 because of its immediate proximity to the Tasmanian Gateway between the STR and Antarctica and its exposure to the Antarctic Circumpolar Current thereafter. The transition from Eocene siliciclastic sediments to pelagic carbonate, as the basin sank rapidly in the earliest Oligocene, was more rapid than in the less current-swept and expanded sequences at Site 1168.

During the Early Cretaceous, the eastern Site 1172 was in the east Gondwana block consisting of Australia, the Lord Howe Rise, and the Campbell Plateau well away from the TASZ. Seismic data suggest that dipping and faulted Early Cretaceous sediments exist at depth. It is probable that a highly reflective sequence above these sediments consists of Late Cretaceous breakup volcanics, perhaps including the undated rhyolite dredged from the eastern scarp of the ETP (Exon et al., 1997a). According to Royer and Rollet (1997), breakup began to form the ETP during the Late Cretaceous (75–65 Ma), both to the plateau’s west and east. The plateau moved east-northeast relative to Tasmania and the STR, initially with the continental block of the Lord Howe Rise and Campbell Plateau. However, this block soon separated, leaving the Tasman Sea oceanic crust to the east of the ETP. In the west, some oceanic crust formed between the ETP and the STR, forming L’Atalante Depression, and crustal thinning occurred between the ETP and Tasmania, eventually forming the East Tasman Saddle.

Although the ETP formed in the Late Cretaceous and might well have had a very different subsidence history from the other Tasmanian blocks drilled during Leg 189, this proved not to be the case by the close similarity between the two Pacific Ocean Sites 1172 and 1171. At both sites, Paleocene and Eocene sediments are similar shallow-marine (neritic) siliciclastics, and at both sites there was rapid subsidence and a switch to deposition of pelagic carbonate beginning in the earliest Oligocene. The plateau had been planated by erosion and subject to latest Cretaceous and Paleogene deposition, with siliciclastic sediment coming from the marginal granitic highs and perhaps from Tasmania, if the East Tasman Saddle subsided late. An additional feature of the ETP was the formation of a large hot spot volcano in its center during the late Eocene. According to Quilty (1997), calcareous microfossils show that the upper part of this 1500-m-high guyot, the Cascade Seamount, was in shallow-marine depths during the late Eocene. This clearly conflicts with the evidence of upper bathyal deposition of latest Eocene sedi-
ments at Site 1172 below the base of the seamount. An explanation awaits postcruise investigation.

A tabulation of vital information from ODP Leg 189 and DSDP Leg 29 sites (Kennett and Houtz, 1975) summarizes much of the above (Table T4). It shows that three breakup ages (75, 55, and 34 Ma) affected the various sites in various ways. The first breakup was at 75 Ma for the central and eastern Sites 1171, 281, 1172, and 283 and at 55 Ma for the western and southern Sites 282, 1168, and 280. The last breakup was at 34 Ma on the STR for Sites 1170, 281, and 1171. The subsidence since the Eocene is large on oceanic crust or thinned continental crust (Sites 282, 1168, 1170, 280, and 283) at 3100–3800 m. It is less on the thick continental crust of the central STR and the ETP (Sites 281, 1171, and 1172) at 1600–2500 m. The transition from siliciclastic to biogenic sedimentation is Eocene/Oligocene at most Leg 189 sites in basinal settings in shallow Eocene water depths, but it is Oligocene/Miocene in several Leg 29 sites on local highs in deeper Eocene water depths. This variation is probably caused in part by the position of the CCD relative to the sites during the Eocene to Miocene.

**Evolution of the Tasmanian Gateway**

In the Early Cretaceous, east Gondwana was intact and ocean currents flowed west and north of Australia and east of the continental block of the Lord Howe Rise, the Campbell Plateau, and New Zealand (LCNZ). The situation began to change early in the Late Cretaceous, when an east-west rift caused marine transgression into the Australo-Antarctic Gulf. Despite a continuation of the rift eastward through present-day Bass Strait into the Lord Howe Rise, the Tasmanian-Antarctic land bridge east of the Gulf survived, and the eastern part of the rift filled with nonmarine sediments. By the Late Cretaceous, the northwest-southeast TASZ was well developed and Gulf waters began to transgress southward along it. During the Late Cretaceous at 75 Ma, continental breakup occurred and seafloor spreading began between Australia and the LCNZ. This rift propagated northward forming the Tasman Sea. Final breakup off northeastern Australia was during the Paleocene at ~60 Ma, and thereafter major ocean currents could flow along the eastern coast of Australia, Tasmania, the ETP, the STR, and the Antarctic margin to the south. However, the Tasmanian Land Bridge between Southeast Australia and Antarctica remained essentially intact, separating the Australo-Antarctic Gulf from the Pacific Ocean.

By the latest Paleocene, the areas of continental crust in the land bridge that had been thinned during the Cretaceous—the future Bass Strait, the South Tasman Saddle between Tasmania and the STR, and parts of the TASZ between Antarctica and STR—had subsided and were near sea level. From then on, limited interchange of shallow-marine waters may have occurred between the Australo-Antarctic Gulf and the Pacific Ocean. The plate tectonic reconstructions of Royer and Rollet (1997), Cande et al. (2000), and S.C. Cande (unpubl. data) suggest, and a variety of other tectonic and sedimentary evidence (including that from Leg 189) supports, the idea of a shallow-marine connection during the middle Eocene (Fig. F7). However, the very different character of the shallow-marine Eocene sediments recovered at Sites 1168 and 1170 in the restricted waters of the Gulf, and at Sites 1171 and 1172 in the open waters of the Pacific Ocean, indicates that this interchange was not significant.
However, the same lines of evidence suggest that Antarctica and the STR separated during the Eocene–Oligocene transition (Fig. F6). The ODP sites clearly show a rapid change in the earliest Oligocene to similar open-ocean conditions on both sides of the former Tasmanian Land Bridge, and a shallow-water Antarctic Circumpolar Current was established at that time. By the late Oligocene, the Tasmanian Seaway was hundreds of kilometers wide and at abyssal water depths south of the STR, and a shallow to deep Antarctic Circumpolar Current from the west was eroding older sediments. Nearly all of the former land bridge south of Tasmania had by then submerged, and the expanding current was scouring the ocean floor in places. The Tasmanian Gateway was fully open at all depths by the time the Drake Passage, south of South America, is inferred to have opened to deep water during the early Miocene (Barker and Burrell, 1977) and could accommodate an ever-increasing circumpolar flow. This increasing flow continued through the remainder of the Cenozoic as the Australian mainland and Tasmania moved northward and the Drake Passage opened further. The expanding influence of circumpolar circulation led to bottom-water erosion and winnowing over certain areas and was particularly strong during the late Neogene. The expansion of the Antarctic cryosphere during the middle and late Cenozoic, and its effect of strengthening thermohaline circulation at deep and intermediate water depths, contributed to the deep-ocean erosion and formation of hiatuses in the sequences. Examples of this include the middle Miocene scouring east of Site 1170 that removed the Oligocene and the scouring during the Miocene–Pliocene transition in the southern part of the STR.

Paleocene–Eocene Paleoenvironments: Before the Gateway Opened

Deposition during the Paleocene through early late Eocene (43–36 Ma) was dominated by continental influences. The sequences drilled are probably quite similar to even older underlying Paleogene sequences, which, based on seismic and other evidence, consist of deltaic siliciclastic sediments that kept up with subsidence and compaction as rifting progressed. The southern sequences (Sites 1170 and 1171) provide unusually good records of Antarctic paleoenvironmental conditions at the high-latitude Antarctic continental margin (~67°S), whereas Sites 1168 and 1172 provide comparative records at lower latitudes on the western and eastern margins of Tasmania. At Sites 1170 and 1171, the Paleocene–Eocene dark, fine-grained, organic-rich siliciclastic sediments were deposited on a highly restricted, moderately tranquil, broad shelf near the opening rift between Antarctica and Australia in the extreme southeastern corner of the Australo-Antarctic Gulf (Site 1170) and in the extreme southwestern margin of the Pacific (Site 1171). Benthic foraminiferal assemblages indicate deposition in neritic water depths, probably shallower than 100 m. An absence of sedimentary characteristics indicating turbulence suggests that deposition was below wave base (which may have been shallow in the prevailing equable climatic conditions) and without important current or tidal influences. Persistent reworked early Eocene to Cretaceous radiolarians and organic dinocysts at Site 1170 suggest continuous weathering and erosion of marine sediments of this age in the hinterland.

Highly restricted nearshore conditions in the middle to early late Eocene at all sites are indicated by a wide range of criteria including pervasive pollen and spore assemblages, abundant continuous low-
diversity assemblages of organic dinocysts indicative of eutrophic and brackish surface waters, and limited representation of open-ocean planktonic microfossils. Diverse pollen and spore assemblages are particularly abundant in the Paleocene sequence at Site 1171, indicating particularly strong continental influence with abundant, diverse plant communities. In situ assemblages of planktonic foraminifers and radiolarians are largely absent, diatoms are rare, and calcareous nannofossils are uncommon. Good preservation of calcareous nannofossils suggests that they are uncommon, not because of dissolution, but because of the restricted coastal depositional setting in conjunction with high sedimentation rates. However, the presence of foraminiferal linings suggests dissolution of foraminifers at some levels.

Ventilation on the shelves over much of the region was poor to limited throughout the middle to early late Eocene judging from high TOC, limited bioturbation, and benthic foraminiferal assemblages dominated by agglutinated forms and nodosariids. The sediments at Sites 1168 and 1170 suggest that the eastern, remote end of the narrow, restricted Australo-Antarctic Gulf was poorly ventilated. Low oxygen levels in waters of the eastern Gulf would have developed because of the restricted circulation (2000 km from the open Indian Ocean) and the proximity of inferred abundant terrestrial organic matter sources from the surrounding land masses (including Antarctica), warm climatic conditions, and possible high marine biotic productivity in eutrophic conditions. Ventilation was especially poor at Site 1168, off western Tasmania, as indicated by laminated sediments. Deeper water sediments at nearby Site 282 were also poorly oxygenated. Anoxic to dysoxic depositional environments would be expected within an expanded oxygen minimum zone that extended up onto the continental shelf at Site 1168. Eocene sediments at Site 1170, in the extreme southeastern corner of the Gulf, were also deposited in poorly oxygenated conditions on a tranquil shelf. Here, the absence of laminations and a slight increase in bioturbation in some intervals suggest greater shelf ventilation than at Site 1168, but circulation was almost certainly sluggish.

The poor ventilation in such shallow-water depths at Site 1170 suggests that the Tasmanian Gateway generally was closed to even shallow waters (~100 m) during the middle and early late Eocene, at least in the developing rift basin between Antarctica and the STR. This is supported by the contrasting Eocene record at Site 1171, near the developing seaway on the Pacific side of the Tasmanian land bridge, where the shelf sediments are well bioturbated, suggesting with other evidence that more strongly ventilated conditions existed here than in the Gulf and no oxygen minimum zone was present. If the Tasmanian Gateway had been open widely at shallow depths, there would have been little basin to basin fractionation and, hence, little contrast in sedimentary environments. Middle Eocene sedimentation at Site 1172 bears considerable resemblance to that at Site 1171, but it was in a more oceanic, better ventilated environment within the open Pacific Ocean. The proximity of Site 1172 to the large and newly formed subaerial Cascade Seamount may have increased the speed of bottom currents nearby, thus enhancing ventilation.

The middle through upper Eocene sediment sequence at Sites 1170 and 1171 reveals distinct cycles in physical properties, sediments, and microfossil assemblages. Alternations between dark, poorly bioturbated, nannofossil-poor sediments lacking glauconite and lighter, more nannofossil-abundant bioturbated sediments containing glauconite probably result from changes in water-mass ventilation. Quantitative changes
in dinocyst assemblages are cyclic. The darker sedimentary intervals are associated with higher abundances of dinocysts (including massive monotaxic blooms) characteristic of eutrophic conditions and suggesting high nutrient supply to surface waters. In contrast, dinocysts characteristic of more oligotrophic surface waters dominate the lighter intervals in association with more abundant calcareous nannofossils. Clear cyclicity with probable Milankovitch periodicity is also evident in Th abundance in the logging data.

These middle to late Eocene shelfal cycles almost certainly will be shown to correlate with changes in sediment and biotic characteristics. The cause of the cycles is yet to be determined, but they probably resulted from minor climatic oscillations at high southern latitudes, perhaps associated with small sea-level changes, which caused changes in siliciclastic sediment supply, upwelling, and nutrient supply, and associated changes in bottom-water ventilation. The relative importance of marine vs. terrestrial sources of organic carbon varied at the different margin locations during the Eocene. At Site 1168, terrestrial organic carbon sources dominated, but marine organic carbon dominated at Sites 1170 and 1171, where marine productivity was high in a restricted nearshore setting. In contrast, Paleocene sediments, sampled only at Site 1171 on the southern STR, clearly exhibit a much stronger terrestrial influence with abundant terrestrial plant materials (e.g., pollen and spores). Throughout the Paleocene to middle Eocene, sedimentation kept up with subsidence and compaction.

Evidence for glaciation is completely lacking in the Paleocene and Eocene. Both marine and terrestrial microfossils indicate cool temperate conditions throughout the middle and late Eocene. Calcareous nannofossil assemblages are of relatively high diversity and appear to be slightly warmer in this sector of the Antarctic than at comparable latitudes elsewhere (although almost completely lacking warmth-loving discoasters). Their diversity suggests an absence of seasonal sea ice over the shelf and marine conditions during much of the time. Middle Eocene clay assemblages at Site 1170 are completely dominated by smectite, suggesting warm temperatures, seasonal rainfall, and a predominance of chemical over physical weathering.

Relatively warm, cosmopolitan middle Eocene dinocyst assemblages were in part replaced during the late Eocene by cooler, endemic Antarctic forms. This inferred cooling is consistent with stable isotopic records that indicate progressive cooling of the Southern Ocean during the middle and late Eocene (Shackleton and Kennett, 1975; Stott et al., 1990; Kennett and Stott, 1990). Cooler continental conditions during the late Eocene are indicated by conspicuous increases in illite relative to smectite clays at Sites 1170 and 1171, suggesting a reduction in continental chemical weathering, perhaps in combination with increased tectonism near the expanding rift. Nevertheless, the character and abundance of the organic dinocyst and diatom assemblages throughout the entire middle to upper Eocene suggest that at no time was cooling sufficient to form important seasonal sea ice in this Antarctic region. Pollen and spore records suggest that the middle and late Eocene hinterlands were inhabited by diverse and cool temperate plant communities. Floras were dominated by *Nothofagus*, podocarps, and other forms with an understory of ferns, similar to an approximately coeval floral assemblage from the Weddell Sea sector of Antarctica (Mohr, 1990). Although upper Eocene pollen assemblages appear to represent cooler conditions, they still indicate relative warmth along the Antarctic margin compared with the distinctly cooler Oligocene that followed. Oli-
Eocene–Oligocene Transition: The Gateway Opens

Major paleoenvironmental changes occurred during the Eocene–Oligocene transition, the most profound change in the entire Cenozoic (Kennett, 1977; Zachos et al., 1993), at all four deep sites (Sites 1168, 1170, 1171, and 1172). The sites contain a variably continuous record of this interval, which shows that almost all aspects of the depositional environment changed. The late Eocene is represented by a condensed sequence of continentally influenced glauconite-rich silty claystones to glauconitic muddy siltstones and the early Oligocene by biogenic carbonates. A transitional change upward in the upper Eocene from more muddy to more sandy sediments, associated with increasing glauconite and quartz and the deposition of glauconitic quartz-rich sandy silts ("green sands"), reflects an upward increase in bottom-current activity and winnowing. The near absence of calcareous microfossils in the "green sands" at Sites 1170, 1171, and 1172 made dating difficult. However, dinocysts and diatoms suggest a relatively complete upper Eocene sequence up to and including the "green sands." This observation is supported by the clear upward gradation in lithology into the "green sands," the general succession of microfossil datums, and the unexceptional changes in the assemblages of organic dinocysts, pollen, and spores.

Within the "green sands," despite the winnowing and hiatuses, the angularity of quartz at some levels indicates periods with little reworking. In the upper Eocene, diatoms and benthic foraminifers indicate a slight deepening of the "green sand" environment. With steadily increasing water depths in the early Oligocene, deposition changed to open-water pelagic carbonates. This reflects a change during the early late Eocene to early Oligocene, from siliciclastic to biogenic sedimentation, from a poorly to a well-oxygenated benthic environment, from tranquil to moderately dynamic environments, and from relatively warm to cool climatic conditions. The sequence of change over the Eocene–Oligocene transition is remarkable in its consistency over the width and breadth of the Tasmanian-Antarctic margin, as determined from our four deeply cored sites. Differences in detail are clearly related to individual settings at the time of deposition, such as latitude, tectonic setting, and proximity to the ocean and landmasses.
The glauconitic sediments are strongly bioturbated and were deposited in well-oxygenated bottom waters. The lack of carbonate microfossils in the “green sands” suggests a dissolution episode related to the expansion of the Antarctic cryosphere. This episode is recorded widely in deep-sea carbonate sequences and is associated with the well-known positive oxygen isotopic shift in the early Oligocene (33 Ma) (e.g., Shackleton and Kennett, 1975; Miller, 1991; Zachos et al., 1994). Based on our biochronology, the changes in the sediments suggest the opening of the Tasmanian Gateway to some cool shallow-water flow in the late Eocene and intensifying current flow toward the Eocene/Oligocene boundary. This was followed in the earliest Oligocene by expansion of the Antarctic cryosphere and deep-water interchange between the southern Indian and Pacific Oceans. This interchange heralds the initiation of the circumpolar current in this segment of the Southern Ocean. Although planktonic microfossils indicate climatic cooling during this interval, there is no evidence of glacial activity, such as ice-rafter debris. Indeed, the calcareous nannofossil assemblages suggest somewhat warmer conditions than in sequences at equivalent latitudes elsewhere in the Southern Ocean (Wei and Wise, 1990; Wei and Thierstein, 1991; Wei et al., 1992). The Oligocene clay assemblages at Site 1170 also suggest a transitional climate based on the co-occurrence of both smectite, indicating chemical weathering, and illite, indicating physical weathering.

Water depths throughout the region began to increase rapidly from the lowermost Oligocene upper bathyal depths. They reached lower bathyal depths during the early Neogene with a total water-depth increase averaging 2000 m. Clearly, such a depth increase must reflect rapid subsidence of the STR and the Tasmanian margin during the Oligocene along with expansion of the Tasmanian Gateway. The major and rapid reduction in siliciclastic sediment supply to the margin would also have contributed to the initial depth increase.

The upper Eocene “green sands” in the sequences closest to Antarctica (Sites 1170 and 1171) are overlain, with little gradation, by ooze and chalk of early Oligocene age. Near western Tasmania (Site 1168), a similar sequence shows more gradation upward in the Oligocene. From the earliest Oligocene onward, sedimentation in these sequences was completely dominated by relatively slow deposition of nannofossil ooze and chalks, faster than in the “green sands,” but much slower than during the early and middle Eocene. Although the age of the base of the carbonates requires better constraint, existing stratigraphic data suggest deposition commenced soon after the earliest Oligocene oxygen isotopic shift at 33 Ma. This isotopic shift represents major cooling and the initial major cryospheric development of East Antarctica (Shackleton and Kennett, 1975; Miller, 1991; Wei, 1991; Zachos et al., 1994) and major expansion of the psychrosphere with its deep-ocean circulation (Kennett and Shackleton, 1976). Therefore, the synchronous commencement of biogenic carbonate deposition at all sites appears to reflect major climatic and oceanographic changes that affected broad regions of the STR and Tasmanian margins. This created a more dynamic, well-ventilated ocean with increased upwelling and higher surface-water biogenic productivity that increased rates of sedimentation of calcareous nannofossils and diatoms and decreased preservation of organic carbon. Open-ocean planktonic diatoms replaced neritic diatoms, which suggests coastal upwelling had begun on the STR and Tasmanian margin during the earliest Oligocene. Furthermore, associated cooling of the Antarctic continent apparently decreased weathering rates and
transport of siliciclastic sediments to the margin. The environment of deposition was, thus, transformed from the late Eocene to the earliest Oligocene, from dominance of siliciclastics to dominance of calcareous nannofossils.

Sequences from other areas of the Antarctic margin show a similar drastic reduction in siliciclastics and increase in biogenic sedimentation during the Eocene–Oligocene transition. The lowermost Oligocene is often marked by an increase in biogenic sediments or of biogenic components in otherwise relatively slowly deposited siliciclastic sediments including diamictites (Diester-Haass and Zahn, 1996; Kennett and Barker, 1990; Salamy and Zachos, 1999). However, outside the Tasmanian region, the biogenic component is usually biogenic silica (diatoms) rather than calcium carbonate (calcareous nannofossils and foraminifers). On the shallow (probably neritic) northwest margin of the Weddell Sea, carbonate-free diatom ooze was deposited during the earliest Oligocene, suggesting significant cool-water upwelling (Barker, Kennett, et al., 1988). On the margins at Prydz Bay and southern Ross Sea, diatoms became an important component in diamictites (Barron et al., 1991a, 1991b; O'Brien, Cooper, Richter, et al., 2001).

Why was there such a sharp change from siliciclastic to carbonate sedimentation at the Eocene/Oligocene boundary? A very broad, shallow Australian-Antarctic shelf had been supplied with siliciclastics for tens of millions of years, and even though rifting, subsidence, and compaction had started early in the Cretaceous, sedimentation had kept pace and shallow-marine sediments were rapidly deposited through until the end of the middle Eocene. In the Tasmanian region, there was also subsidence related to the Late Cretaceous opening of the Tasman Sea and uplift on the western and eastern onshore margins in the late Paleocene to early Eocene (O’Sullivan and Kohn, 1997). Our studies show that the peak of Cenozoic tectonism occurred during the latest Paleocene (55 Ma) at Site 1171 and in the middle Eocene (~40 Ma) at Site 1170. Rifting between Australia and Antarctica led to almost complete separation of the continents and fast spreading in the middle Eocene (43 Ma), and this could be expected to increase the rate of subsidence. At Sites 1170, 1171, and 1172, glauconitic and siliciclastic late Eocene sedimentation almost kept up with subsidence until the Eocene/Oligocene boundary (33 Ma), some 10 m.y. after the onset of fast spreading, even though the sedimentation rate was then low.

Subsequently, the rate of subsidence increased at the Eocene/Oligocene boundary, an effect mirroring coeval rapid subsidence that formed the Victoria Land Basin in nearby Antarctica (Cape Roberts Scientific Team, 2000). This subsidence clearly had a regional cause (see “Tectonic Evolution,” p. 45) and reduced the area available for erosion in the Tasmanian region. The contemporaneous climatic cooling would have led to greatly reduced rainfall and, thus, weathering and erosion, further reducing siliciclastic supply. Thereafter, the sea deepened rapidly, and slow pelagic carbonate deposition dominated completely. This appears to have been the most significant interval of sediment starvation along the Antarctic margin.

**Paleogene Margin Carbonates: Interplay between Tectonics and Climate**

The sequences at Sites 1170 and 1171 have revealed a marked difference in the Eocene–Oligocene sediment transition as compared with other parts of the Antarctic margin. As far as we can tell, no other mar-
gin sectors experienced pelagic carbonate deposition immediately following the Eocene/Oligocene boundary. Other areas experienced deposition of biosiliceous sediments or more slowly accumulating siliciclastic sediments with an increased siliceous biogenic component. The environment at the Tasmanian-Antarctic margin apparently favored biogenic carbonate preservation and relatively low biosiliceous productivity. Here, even Eocene siliciclastic sediments generally contain a better record of better preserved calcareous nannofossils and foraminifers than elsewhere. These observations suggest different climatic regimes in different sectors of the Antarctic margin during the Eocene and Oligocene. Antarctic circumpolar climatic and oceanographic similarity, a hallmark of the modern Antarctic, did not exist during the Paleogene. Biogeographic evidence from calcareous nannofossils and lack of any offshore evidence for glaciation in the Tasmanian sector indicate that conditions were slightly warmer than in other margin sectors, even during the Oligocene. The earliest Oligocene was a time of major cryosphere expansion in the southern Indian Ocean sector and in the southern Ross Sea. Thus, Antarctic circumpolar circulation was still insufficiently developed in the Oligocene to unify the character of Antarctic paleoenvironmental change.

Why are carbonates generally better preserved on the STR in the Paleogene than elsewhere on the Antarctic margin? This region may have been under the strong influence of warm low-latitude surface waters carried southward along the eastern margin of Australia by the East Australian Current and southward around western Australia into the Australo-Antarctic Gulf. Southward flow of warm waters along the east Australian margin would have been enhanced by constriction in the Indonesian Seaway in the Oligocene (Hall, 1996). These warm tropical waters would have been relatively saline and, thus, would have helped promote production of deep waters. Hence, this sector of the margin may have operated in an antiestuarine mode (Berger et al., 1996) marked by a downward flux of deep waters and an inward flow of surface waters, as in the modern North Atlantic. In this case, upwelling of nutrient-rich waters is diminished and carbonate accumulation is favored. Other sectors of the Antarctic margin, marked by strong carbonate dissolution at shallow water depths and high biosiliceous accumulation, may have operated in estuarine mode, marked by an upwelling of nutrient-rich deep waters and an outflow of surface waters. There, carbonate dissolution is favored by the upwelling of old, deep, low-alkalinity, high pCO₂ waters such as in the modern north Pacific Ocean.

A major strengthening of oceanic thermohaline circulation occurred at the climatic threshold of the Eocene-Oligocene transition. This resulted largely from the major cooling and cryospheric development of Antarctica (Kennett and Shackleton, 1976). This cooling, in turn, led to increased aridity of the continent and a major reduction of freshwater flow to the surrounding continental margin, which is reflected by marked reduction in the transport of siliciclastic sediments to the Antarctic margin. Surface waters near the margin would therefore have increased in salinity. A major positive feedback almost certainly would have resulted, with further strengthening of bottom-water production and expansion of the oceanic psychrosphere (deep-ocean circulation). Thus, the delivery of high-salinity surface waters to the STR sector of the Antarctic margin, caused by its unusual plate tectonic setting, may well have especially enhanced bottom-water production and, in turn, increased carbonate-biogenic accumulation on the margin.
Southern Ocean Development and Paleoceanography

Drilling during Leg 189 was conducted to test the hypothesis formulated during DSDP Leg 29 (Kennett et al., 1974; Kennett, Houtz, et al., 1975; Kennett, 1977) that initial development and evolution of the Antarctica cryosphere during the middle and late Cenozoic resulted from thermal isolation of Antarctica by the development of the Antarctic Circumpolar Current and the Southern Ocean. The Cenozoic expansion of the Southern Ocean resulted from plate tectonic movements that caused northward movement of Australia and its southern continental extension—Australia and the STR—and the opening of Drake Passage (Weissel and Hayes, 1972; Barker and Burrell, 1977; Lawver et al., 1992; Cande et al., 2000). The opening of the Tasmanian Gateway created initial thermal isolation and resulted in the major cooling of Antarctica that also produced, through feedback mechanisms, the first ice sheets on at least some sectors of the continent. The four major sites drilled during Leg 189 penetrated to middle Eocene or even Upper Cretaceous sediments, thus providing a climatic and paleoceanographic record for the last 40 to 70 m.y., depending on the site. The sediment sequences reveal a remarkably coherent regional picture reflecting major paleoceanographic changes, especially during the mid-to late Paleogene and continuing into the Neogene, resulting from critical plate tectonic changes related to final separation of the STR from East Antarctica.

Paleogene

Changes in the sediment records drilled during Leg 189 are consistent with plate tectonic reconstructions (Royer and Rollet, 1997; Cande et al., 2000). These reconstructions suggest that before the late Eocene, the Tasmanian land bridge effectively blocked even shallow water connections between the Australo-Antarctic Gulf and the southwest Pacific Ocean (Fig. F24). Initial opening of the Tasmanian Gateway to shallow waters occurred some time in the late Eocene after ~37 Ma, and deeper waters by 33 Ma (earliest Oligocene) (Fig. F25). The two crucial effects of plate tectonics were therefore the initial development of a gateway to shallow waters, followed by subsidence of the STR and establishment of deep interocean communication. The sediment sequences recovered during Leg 189 suggest that major subsidence of the margins cored was very rapid, beginning near the Eocene/Oligocene boundary and becoming well advanced by the earliest Oligocene. The gateway was then fully open (Fig. F25), and the Tasmanian Seaway, involving both shallow to abyssal water flow, continued to expand during the remainder of the Cenozoic (Fig. F26) as it does today.

Major reorganization of Southern Ocean circulation occurred during the Eocene–Oligocene transition, as proposed by Kennett, Houtz, et al. (1975), Kennett (1977), and Murphy and Kennett (1986), as Antarctic circumpolar circulation commenced through the developing Tasmanian Seaway. Until the early late Eocene (Fig. F24), no Antarctic Circumpolar Current existed to interfere with the influence of the southward-flowing warm-subtropical arm of the South Pacific gyre (East Australian Current). These warm waters were transported close to Antarctica, warming this region and contributing toward the well-known relative warmth of the continent before the late Eocene, a trend supported by Leg 189 data. The opening of the Tasmanian Gateway and the development of Antarctic circumpolar circulation closely coincides
with major cooling and cryospheric development of Antarctica during the Eocene–Oligocene transition (Shackleton and Kennett, 1975; Miller, 1991; Zachos et al., 1994). This allowed relatively cooler waters from the Australo-Antarctic Gulf into the South Pacific as the Antarctic Circumpolar Current, which led to initial decoupling of the warm-subtropical gyre from the Southern Ocean (Fig. F25) and cooling of South Pacific waters at high latitudes (Kennett, 1977, 1978; Murphy and Kennett, 1986). The decoupling strengthened as the Tasmanian Seaway continued to open during the Oligocene (Fig. F26) and throughout the remainder of the Cenozoic, with the expansion of the Southern Ocean. The ever-increasing strength and width of the Antarctic Circumpolar Current led to increased Cenozoic thermal isolation of Antarctica that, in turn, led to further positive feedbacks reinforcing Antarctic cooling and cryosphere expansion. Although the late Oligocene through Neogene record of this climatic evolution was not immediately apparent during shipboard investigations, we expect that this will be revealed as a result of postcruise isotopic and quantitative microfossil studies.

Major changes in the sediments from Leg 189 are consistent with the hypothesis that major Antarctic cooling occurred during the Eocene–Oligocene transition at the time of the Antarctic Circumpolar Current development through the Tasmanian Gateway. The most conspicuous sedimentological change for the entire last 65 m.y. was the Eocene–Oligocene transition from rapidly deposited siliciclastic sediments to pelagic carbonates. In Leg 189 sequences, the transition is associated with an increase in bottom currents, while the margins were still relatively shallow, in neritic to upper bathyal depths, leading to a conspicuous reduction in sedimentation rates and deposition of glauconitic silts and sands. Widespread hiatuses in the lower to mid-Oligocene indicate increased and pervasive current activity down to abyssal depths. Increased current strength in the narrow Gateway resulted in increased thermohaline circulation synchronous with psychrospheric development. This, in turn, was linked to enhanced bottom-water production around the now seasonally freezing Antarctic margin (Kennett and Shackleton, 1976).

As discussed above (see “Eocene–Oligocene Transition,” p. 53), the relatively sudden decrease in deposition of siliciclastic sediments along the margins of the Tasmanian land bridge is inferred to have resulted largely from sediment starvation caused by a dramatic decrease in precipitation, humidity, chemical weathering, and, hence, run-off and sediment supply from Antarctica associated with the major cooling. This change corresponds to the large positive shift in oxygen isotopic values detected globally in the deep ocean, which reflects both cooling of the deep ocean upon development of the psychrosphere (deep-ocean cool waters) and significant ice accumulation on Antarctica, initiating the cryosphere. The change closely coincides with rapid subsidence of the STR and the Tasmanian margin, which also reduced the supply of siliciclastic sediments, led to open-ocean conditions and encouraged upwelling, and increased biogenic sedimentation. Increased upwelling elsewhere, over broad areas of the Antarctic margin, led to the onset of biosiliceous sedimentation, unlike the pelagic carbonate sedimentation of the Tasmanian margin.

Major glacial development of the Antarctic is inferred to have begun in the earliest Oligocene in a number of areas from the evidence of diamicites (Barron et al., 1991b; Hambrey et al., 1991; Cape Roberts Science Team, 2000) and ice-rafted sediments (Hayes, Frakes, et al., 1975; Barker, Kennett, et al., 1988; Zachos et al., 1992). Although early
Oligocene mountain glaciers existed on Tasmania, it remained vegetated (Macphail et al., 1993). Shipboard investigations during Leg 189 revealed no evidence for Oligocene glacial activity on the Antarctic margin in the offshore Tasmanian region. This is consistent with the observations made during DSDP Leg 29 (Kennett, Houtz, et al., 1975). Furthermore, evidence is lacking for early Oligocene glacial activity at DSDP Site 274 in an equivalent sequence on the conjugate Antarctic margin near Cape Adare, where, even in the late Oligocene, glacial activity was extremely rare (Piper and Brisco, 1975). Our combined results strongly suggest that this sector of the Antarctic margin was relatively warm compared with others, especially in the Kerguelen sector in the southern Indian Ocean (see “Paleogene Margin Carbonates,” p. 55).

We present the hypothesis that relative warmth of the Tasmanian region resulted from long-term transport of heat toward the Southern Ocean by the warm East Australian Current (Figs. F24, F25). However, the influence of this warm current apparently did not extend into the southern Ross Sea in the early Oligocene, when marine diamicrites were deposited at 77°S at Cape Roberts (Cape Roberts Scientific Team, 2000). Thus, a strong meridional climatic gradient existed in the Ross Sea sector of Antarctica. Indeed, a corollary of Leg 189 interpretations is that Antarctica was clearly marked by strong regional differences in climate during the Oligocene.

Earlier ideas of continent-wide ice sheets of present-day proportions in the Oligocene are unlikely based on descriptions of several margin sediment sequences drilled during the DSDP and ODP programs (e.g., Kennett and Barker, 1990; Hayes, Frakes, et al., 1975), including results from Leg 189. This probably includes the earliest Oligocene interval of inferred major ice growth (Zachos et al., 1992), evidence for which is also apparently lacking in the Leg 189 sequences. This conclusion appears reasonable considering that the Antarctic Circumpolar Current was still developing in the Oligocene, so its unifying circumpolar influence probably had not developed until the Neogene. Until then, regional climatic differences probably existed around the margin. Indeed, if it is correct that deep Antarctic circumpolar circulation formed in the earliest Miocene (Barker and Burrell, 1977), fundamental paleoceanographic changes associated with this development may have been the basis for differentiation of the Paleogene and Neogene by earth scientists in the dawn of the scientific era.

Neogene

Neogene sedimentation at Leg 189 sites on the STR and the Tasmanian margin was completely dominated by nannofossil oozes with a significant foraminiferal component. Pelagic carbonate sedimentation was largely continuous, except during the late Miocene and earliest Pliocene, at a number of sites. The Miocene–Pliocene transition is missing in a hiatus at Sites 1169 and 1171, and the lower upper Miocene is missing at Site 1168. Otherwise, the lower and upper Miocene and the Pliocene to Quaternary appear to be largely complete in the sequences. The uppermost Miocene hiatus appears to have resulted from increased thermohaline circulation associated with Antarctic cryosphere expansion at that time (Hodell et al., 1986). Altogether, the Neogene sequences cored during Leg 189 provide a fine suite of sequences in present-day temperate (cool subtropical) and subantarctic water masses of the Southern Ocean. These represent a treasure chest for high-resolution Neogene paleoclimatic and biostratigraphic investigations of the
Southern Ocean. The Neogene carbonates exhibit changes that record changing environmental conditions in response to the northward movement of the STR, Tasmania, and the ETP from Antarctica and shifting positions of the Subtropical Convergence and the Subantarctic Front.

The pelagic carbonates accumulated at relatively low rates (~2–4 cm/k.y.) typical of the open ocean. Relatively low-diversity benthic foraminiferal assemblages indicate deposition in abyssal depths under generally well-ventilated conditions characteristic of the Antarctic Circumpolar Current region. Other than a small, pervasive clay fraction, siliciclastic sediments are absent throughout the Neogene, except in the lower Neogene of Site 1168, which is the site closest to a present land mass. Nannofossil oozes are conspicuously pure white on the STR in the lower Neogene, which corresponds to a period when the STR was well clear of the siliciclastic influences of Antarctica and yet had not come under the late Neogene influence of increasing aridification and associated dustiness of Australia. Diatoms are consistently present throughout the Neogene carbonates but exhibit a distinct increase in abundance and diversity after the middle Miocene. This almost certainly reflects an increase in upwelling within the Southern Ocean at that time in response to the well-known expansion of the Antarctic cryosphere. A marked increase in carbonate ooze deposition during the early Pliocene at Sites 1169 and 1170, on the southeastern STR, is not observed at other sites, suggesting local concentrations of calcareous nannofossils rather than any regional trend like that in the southwest Pacific (Kennett and von der Borch, 1986). During the latest Neogene, planktonic foraminifers become much more important relative to calcareous nannofossils. This may reflect increased winnowing by deep currents and/or a decrease in relative importance of calcareous nannofossils compared to planktonic foraminifers during the late Neogene.

Postcruise investigations of Leg 189 Neogene sequences will lead to a significant increase in understanding of paleoclimatic and paleoceanographic history of the Southern Ocean. Upper Neogene sections have been satisfactorily spliced from multiple cores from four of the sites (Sites 1168 and 1170–1172) to provide essentially continuous paleoclimatic records. Pervasive sedimentary cycles are apparent throughout the entire Neogene, based on observations of the sediment record and changes in the physical properties of the sediments. Shipboard investigations of clay assemblages suggest relatively warmer conditions during the early Neogene until ~15 Ma. After that, clay assemblages suggest general regional cooling. During the late Neogene, clays became increasingly important in the pelagic carbonates, in part because of increasing dust transport from Australia. A distinct influx of kaolinite in several sites, including the southern STR, during the late Pliocene and Quaternary probably reflects increasing southeastward wind transport of relict clays from an increasingly arid Australia. The uppermost Neogene sediments at Site 1172, which is downwind from Tasmania, exhibit distinct cycles in clay abundance in the biogenic oozes, almost certainly in response to glacial-interglacial oscillations in Australian continental aridity.

Open circles with dots = Leg 189 sites. Late Cretaceous oceanic crust was covered with deep Pacific Ocean, and Eocene oceanic crust with bathyal ocean. Most of the Tasmania-South Tasman Rise region was covered in shallow seas. Shallow-water connections between the restricted Australo-Antarctic Gulf to the west and Pacific Ocean may have been established both north and south of the South Tasman Rise.
Figure F7. Paleogeographic map of the Tasmanian region at the Eocene/Oligocene boundary (33.5 Ma) based partly on Royer and Rollet (1997, fig. 8) and Leg 189 results. Solid circles = DSDP Leg 29 sites. Open circles with dots = Leg 189 sites. Most oceanic crust was covered with deep water, and most of the Tasmania/South Tasman Rise region was covered in bathyal seas. A deep-water connection between the restricted Australo-Antarctic Gulf to the west and the Pacific Ocean had just been established south of the STR, allowing the onset of Antarctic circumpolar circulation.
Figure F8. Predrilling cross-sections from seismic profiles across the region (after Hill et al., 1997b; Exon et al., 1997a, 1997b) showing DSDP and proposed high-priority ODP sites. P1 = West Tasmania; P2 and P3 = South Tasman Rise; and P4 = East Tasman Plateau. Site locations are shown in Figure F3, p. 68.
Figure F9. Map of structures and minimum sediment thickness of the area west and south of Tasmania after Hill et al. (1997a), based on multichannel seismic profiles. ODP and DSDP sites are shown. TWT = two-way traveltime.
Figure F10. Sketch map of Cretaceous and Paleogene movements, relative to a fixed Tasmania, of the western South Tasman Rise block, eastern South Tasman Rise block, and East Tasman Plateau (modified from Exon et al., 1997b, based on Roger and Rollet, 1997).
Figure F11. The oceanographic fronts in the Southern Ocean south of Tasmania after Rintoul and Bullister (1999). STF = Subtropical Front; SAF = Subantarctic Front; and PF = Polar Front.
Figure F12. Postdrilling interpretation for local seismic profile SO 36-47, across Site 1168, showing broad ages and lithostratigraphic units. The site is on a gentle slope to the west. Note the thick Oligocene sequence. The long-wavelength hummocks in the late Eocene may represent delta distributaries. There is almost no seismic character in the younger sequences, but three age/lithostratigraphic boundaries are marked by reflectors: Me, Oe, and El. Siliciclastic material has been shed from a ridge upslope into the Eocene and Oligocene sequences. TD = total depth.
Figure F13. Postdrilling interpretation for local seismic profile AGSO 125-14, across Site 1170, showing broad ages and lithostratigraphic units. This shows the site’s position just west of the high central block and the evidence of Miocene scouring that removed the Oligocene and late Eocene sequences. Note the thick Pliocene-Pleistocene and the reduced Oligocene sections at this site. TD = total depth. M = marl.
**Figure F14.** Postdrilling interpretation for local seismic profile AGSO 202-5, across Site 1171, showing broad ages and lithostratigraphic units. The site is in a north-south strike-slip basin on the central block of the South Tasman Rise (15 km), just west of the trace of the Balleny Fracture Zone (and the eastern block of the Rise). It is the only site that penetrated the Paleocene, and the relationships at the Paleocene/Eocene unconformity indicate that the fracture zone’s last movement was in the late Paleocene. This probably represents the time of initial spreading to the south. Note the thick Eocene, the very thin Oligocene, and the thin Pliocene–Pleistocene sections at this site. TD = total depth. M = marl.

![Postdrilling interpretation for local seismic profile AGSO 202-5](image_url)
Figure F15. Postdrilling interpretation for local seismic profile AGSO 125-4, across Site 1172, showing broad ages and lithostratigraphic units. Drilling directly dated the three upper unconformities (A–C), and helped control the possible ages of the lower unconformities (D and E). Note the thick middle Eocene and Miocene to Holocene, and the virtually absent Oligocene and late Eocene sections at this site. TD = total depth.
Figure F16. Summary of lithologies, Sites 1168 through 1172. TD = total depth.
Figure F17. Comparison of major age stratigraphic units by depth for Sites 1168 through 1172. TD = total depth. * = straddles the Eocene/Oligocene boundary.
Figure F18. Summary stratigraphic and sediment facies for Sites 1168 through 1172, arranged west to east. Major lithologies against time show major hiatuses.

- Organic and glauconite bearing silt claystone/clayey siltstone
- Organic bearing, nannofossil bearing, silty claystone/clayey siltstone
Figure F19. Sedimentation rate summary curves for Sites 1168 through 1172. Note the marked change in sedimentation rates in the late middle Eocene at two southern sites (Sites 1170, 1171).
**Figure F20.** A. Smoothed GRA bulk density for Sites 1168, 1170, 1171, and 1172 vs. depth. Data from multiple holes were combined for Sites 1170, 1171, 1172 to produce a complete profile. Stratigraphic boundary depths were taken from “Biostratigraphy” in the individual site chapters. (Continued on next page.)
Figure F20 (continued). B. Smoothed MST magnetic susceptibility data for Sites 1168, 1170, 1171, and 1172 vs. depth. Data from multiple holes were combined for Sites 1170, 1171, 1172 to produce a complete profile. Stratigraphic boundary depths were taken from biostratigraphy section in the individual site chapters.
Figure F21. Downhole natural gamma and medium resistivity results from Holes 1168A, 1170D, 1171D, and 1172D. Higher gamma values are often indicative of an increased terrigenous component and/or organic material in the sediment, whereas higher resistivities are often associated with increased lithification and/or decreased porosity. The distinct lithologic change close to the Eocene/Oligocene boundary, from siliciclastic glauconitic claystone to nannofossil chalk and ooze, can be clearly seen in Holes 1168A (~260 mbsf), 1171D (~270 mbsf) and 1172D (~360 mbsf).
Figure F22. Summary of organic geochemistry results. The upper panel shows carbonate content (in weight percent CaCO$_3$), whereas the lower panel presents total organic matter content and hydrogen indices. Also shown are regional correlations and approximate location of lithostratigraphic units and age.
Figure F23. Summary of interstitial water geochemistry results for Sites 1168, 1170, 1171, and 1172. The upper panel shows Cl⁻ and methane profiles. Intervals with Cl⁻ values less than mean seawater (i.e., fresher waters) are shaded. The lower panel shows concentration-depth profiles for selected interstitial water constituents. The approximate location of the Eocene/Oligocene (E/O) boundary is also shown.
Figure F24. Schematic diagram showing inferred surface-water circulation of the Australian-Antarctic region during the middle Eocene (43.7 Ma) with the Tasmanian Gateway closed. Plate tectonic reconstruction is modified from Cande et al. (2000). Note the influence of the East Australian Current on the Antarctic margin in the absence of Antarctic circumpolar circulation. Weak gyral circulation is inferred in the highly restricted Australo-Antarctic Gulf. ODP Leg 189 and DSDP Leg 29 site locations are indicated. N.Z. = New Zealand.
Figure F25. Schematic diagram showing inferred surface-water circulation of the Australian-Antarctic region during the earliest Oligocene (33 Ma). Plate tectonic reconstruction is modified from Cande et al. (2000). At this time, the Tasmanian Gateway was initially open to deep-water Antarctic circumpolar circulation between the South Tasman Rise and Antarctica. Note that early development of Antarctic circumpolar circulation began to decrease the influence of the East Australian Current on the Antarctic continental margin. N.Z. = New Zealand.
Figure F26. Schematic diagram showing inferred surface-water circulation of the Australian-Antarctic region during the late Oligocene (26 Ma). Plate tectonic reconstruction is modified from Cande et al. (2000). At this time, the Antarctic cryosphere had increased significantly. The expansion of the Antarctic Circum-polar Current (ACC) continued as the South Tasman Rise and Tasmania moved northward from Antarctica. Note increasing decoupling of the East Australian Current from the Antarctic margin associated with the increasing strength of the ACC. N.Z. = New Zealand.
